the respiratory systolic fluctuation decreased slightly (by 10 mm., 16 mm., and 14 mm. respectively), but did not return even to near normal limits during the period of observation. After the other three injections there was a slight decrease in the fluctuations (6 mm., zero, and 2 mm.). With aminophyllin, such relief as occurred seemed to follow more a moderate fall of the expiratory peak of the systolic pressure than a decrease in the respiratory fluctuation.

Two months later, after she had been asthma-free for five weeks, the respiratory systolic fluctuation was 8 mm.

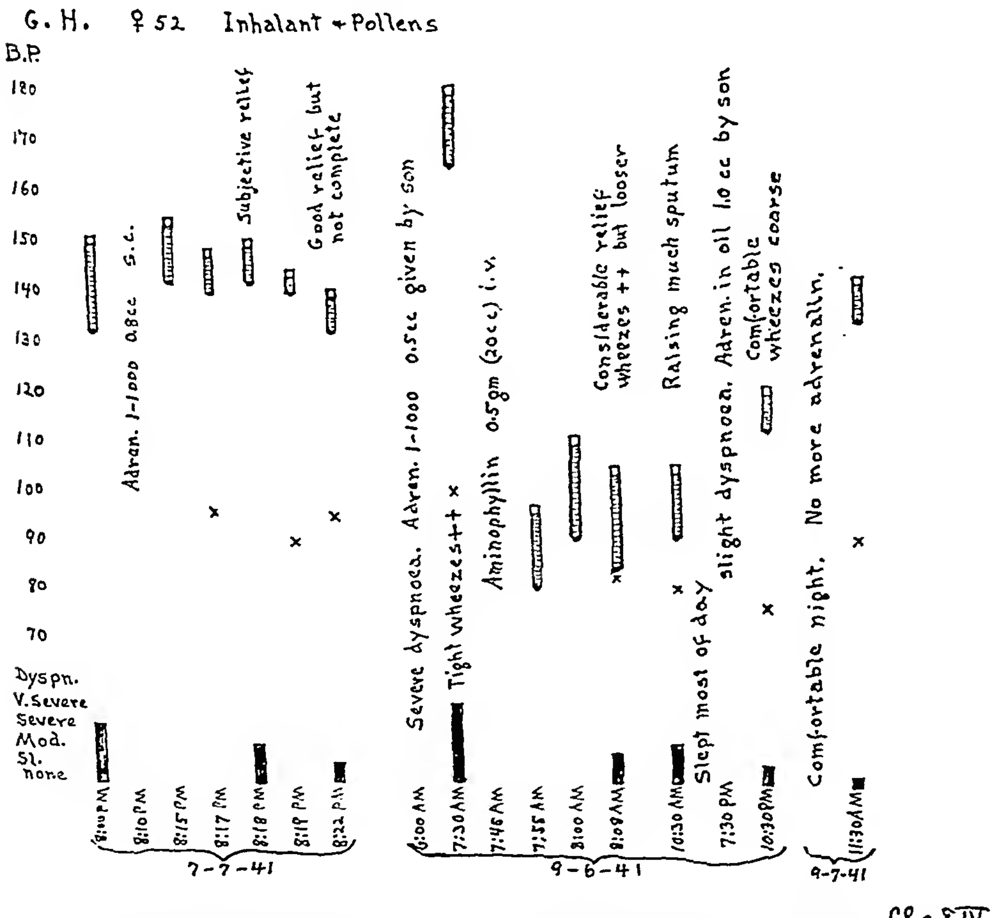

Chart IV.—Comparative effects on the respiratory systolic fluctuation of epinephrine and of aminophyllin, administered to a patient in separate paroxysms of asthma.

DISCUSSION

As a result of observations reported by Osgood in two previous articles,[4, 5] he believes that the enhanced respiratory fluctuation of the systolic blood pressure found in bronchial asthma is dependent upon and is an indirect measure of the obstruction to respiration and that a return of this fluctuation to normal signals a reduction of the obstruction. Consequently the observed return of this fluctuation to normal, when relief follows epinephrine, would indicate that the relief with this drug is brought about by a direct release either of bronchial

spasm, or of bronchial edema, or of both. When relief is obtained with aminophyllin, judging from the fact that the respiratory systolic fluctuation decreases but does not return entirely to normal limits, we may conclude that there has been clinical evidence of *some* bronchodilatation with this drug also. That the fluctuation does not decrease appreciably, either after epinephrine or aminophyllin, when no relief is secured, indicates that the bronchial obstruction has not been released.

Since relief with aminophyllin does not appear to depend wholly on bronchodilatation, the question arises as to what mechanism is here involved.

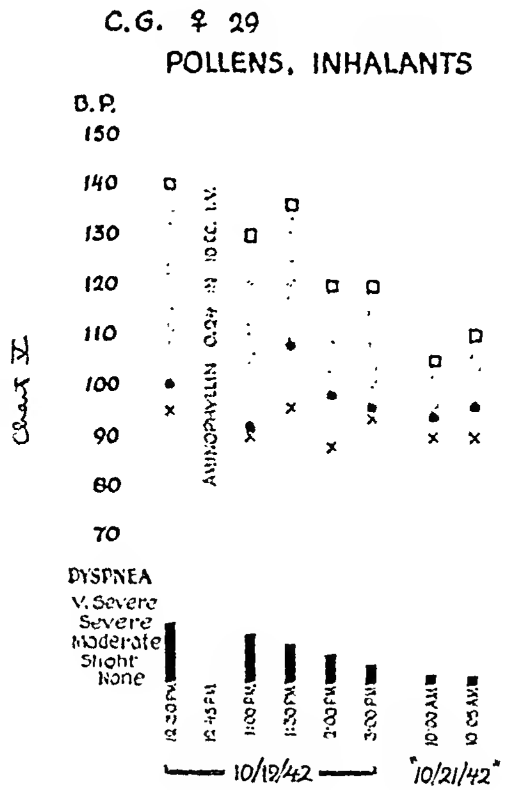

Chart V.—The effect of aminophyllin on the respiratory systolic fluctuation when relief is secured.

Those patients who were given aminophyllin were in general suffering from more obstinate asthma than those given epinephrine, and many were "epinephrine-fast." It is possible that in some of these patients retained bronchial secretion tended to maintain partial obstruction, thus continuing the wide respiratory fluctuation of the systolic blood pressure. This would not, however, explain the rather uniform persistence of a wide fluctuation after aminophyllin with relief.

If the asthmatic patient continued normal respiratory movements during a paroxysm of bronchial obstruction, there would be insufficient ventilation to eliminate properly CO_2 or to take in O_2; hypercapnia and anoxia would result. Leaving out of consideration the possibility that nerve impulses from the lungs, initiated by the respiratory obstruction itself, induce dyspnea, it can be assumed that the asthmatic dyspnea is a reflex response of the respiratory centers, de-

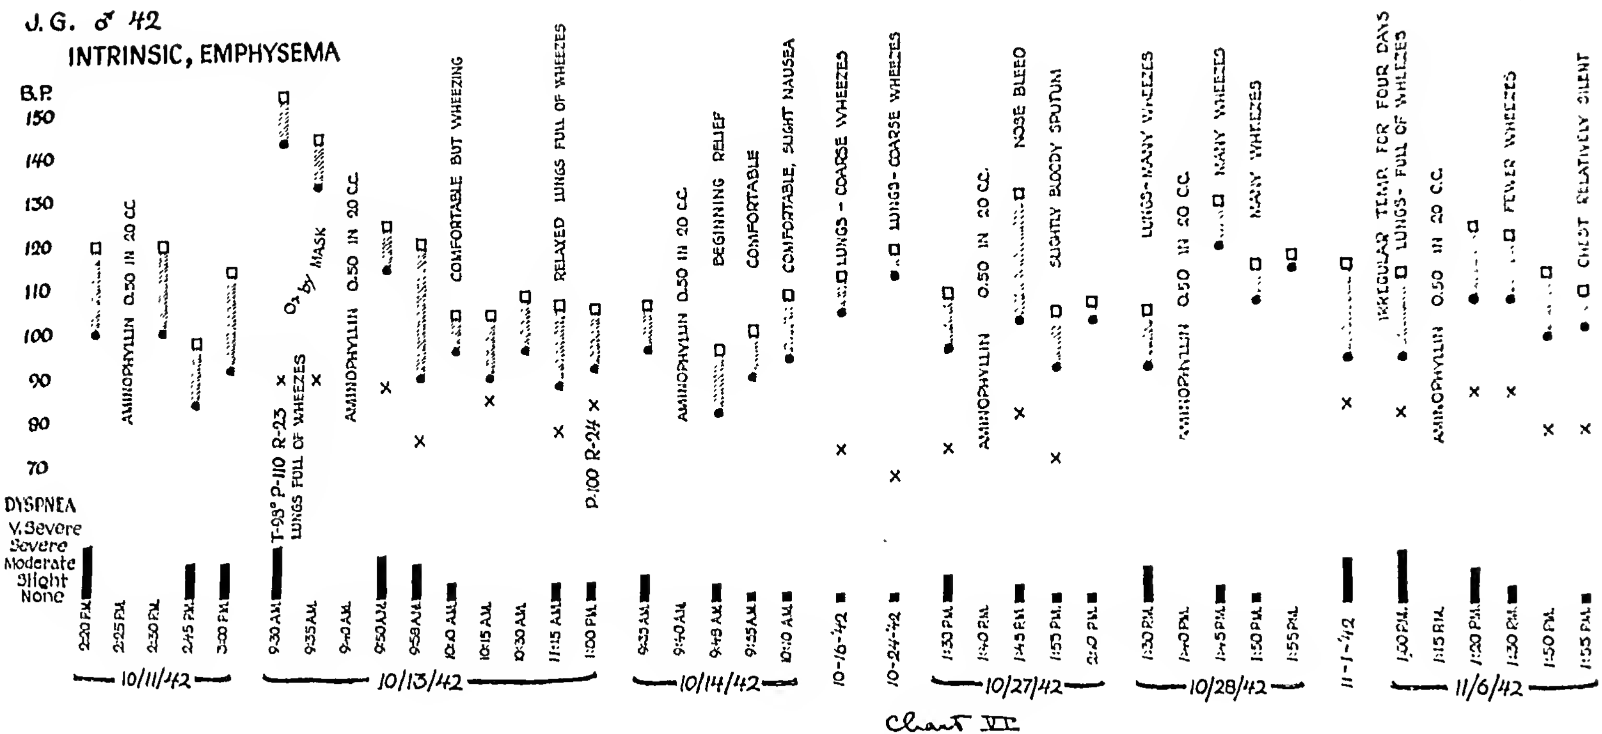

Chart VI.—The effect of aminophyllin on the respiratory systolic fluctuation with variable relief.

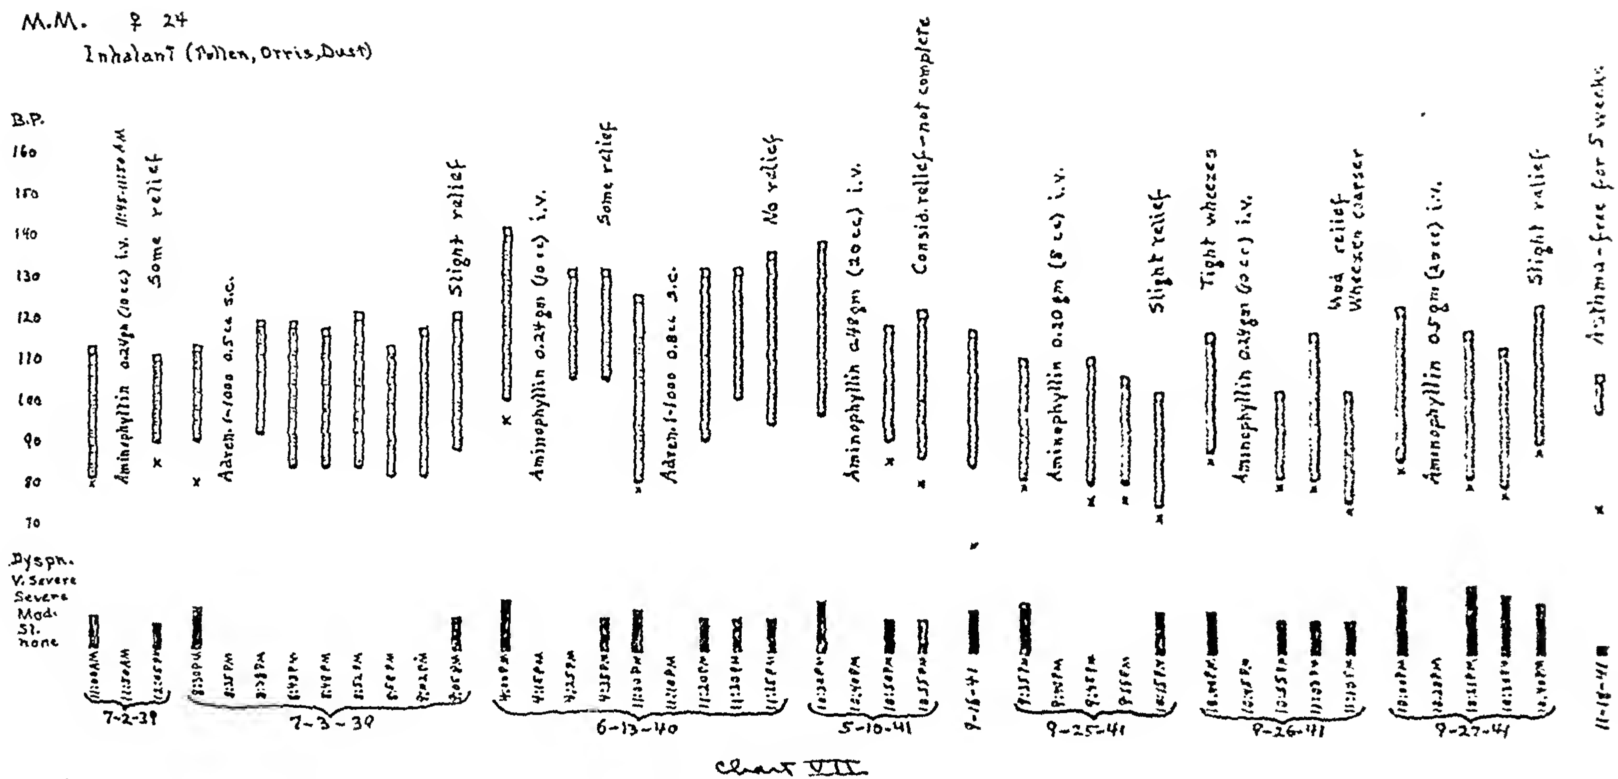

Chart VII.—The effects of epinephrine and of aminophyllin on the respiratory systolic fluctuation in an asthmatic patient refractory to treatment.

pendent primarily upon the CO_2 content of the blood and secondarily on O_2 saturation. If oxygen is administered, the patient will experience some subjective relief even though the bronchial obstruction is not released. The asthmatic type of breathing persists, because if it did not, CO_2 would accumulate and soon stimulate the respiratory centers to further activity. Aminophyllin is said to produce vasodilatation of the coronary arteries (F. M. Smith, et al.,[6] Essex, et al.[7]) and of the renal arteries (Deschamps[8]) and to increase the total blood flow through the pulmonary circulation (Mitchell[9]). The last action would expose more blood per minute to the alveolar membrane and so promote more rapid elimination of CO_2 and greater oxygenation of the blood. The respiratory centers would be subjected to the lesser stimulus of a lower blood CO_2 content; the anoxia would be reduced. The patient would then experience an appreciable diminution of his dyspnea, even though the bronchial obstruction was only partially released.

An alternative supposition, from a purely speculative point of view, is that part of the physiologic response in human beings which eventuates in bronchial asthma may be a pulmonary arteriolar spasm, similar except for reversibility to that occurring in rabbit anaphylaxis. The obliteration of this arteriolar spasm by the vasodilating action of aminophyllin would then explain in part the relief of asthma by this drug. This hypothesis invites further study.

In either case, an improved blood flow throughout the pulmonary circuit appears to us to be an important, if not the principal, factor in the relief of asthma by aminophyllin.

Our interpretation of the data presented here is highly theoretical and open to discussion. It raises a number of questions. Does the venous pressure fluctuate with respiration in asthma, and if so, what time relation does its fluctuation bear to the arterial fluctuation, and how is it affected by epinephrine and aminophyllin? What are the variations of the intrathoracic pressures in asthmatic patients as related to the respiratory systolic fluctuation, and to relief? What changes occur in the blood CO_2 and the arterial O_2 saturation, and in the pulmonary circulation time before and after these drugs? These are answerable only by investigation. It is hoped that others will make additional observations along these lines, testing our findings and carrying them further.

CONCLUSIONS

Following the subcutaneous injection of epinephrine, if relief from asthma is obtained, the respiratory systolic fluctuation decreases to or near the normal.

Following the intravenous injection of aminophyllin, if relief is obtained, the respiratory systolic fluctuation may decrease, but not to an extent comparable to that with epinephrine.

Following either drug, if relief is not secured, the respiratory systolic fluctuation remains wide.

It is suggested that the principal action of aminophyllin in relieving asthma is by increasing the blood flow through the pulmonary circulation by vasodilatation and that its bronchodilating effect is of secondary importance.

A generous supply of aminophyllin was furnished us by G. D. Searle & Co. for use in our studies.

POLLEN SURVEYS IN THE UNITED STATES: A CRITICAL REVIEW*

Philip M. Gottlieb, M.D., and Erich Urbach, M.D., Philadelphia, Pa.

CAREFUL etiologic diagnosis and specific therapy of hay fever presuppose an accurate knowledge of the pollen in the air in the patients' vicinity capable of producing pollinosis, and of the seasons during which the pollen is present. Although in a given community a relatively few plants are responsible for the vast majority of pollen sensitivities, in the remaining cases it is precisely due to the pollens less common, and hence more difficult to appraise, that such information has particular value, since it makes possible the selection of the proper pollens to be used in testing. Moreover, it is a well-known fact that only a small minority of patients are hypersensitive to but one pollen. And even those physicians who elect to use an extract of only one species of pollen for the treatment of a case with multiple hypersensitivities do not deny the necessity for thorough etiologic diagnosis. Furthermore, it is often desirable to compare the symptoms of both treated and untreated patients, particularly those who fail to react to tests despite evidence of clinical hypersensitiveness, or those who react in the absence of such evidence, with available phenologic information.

For all these reasons, the accumulation of dependable data concerning the distribution and pollination times of plants causing pollinosis is a fundamental step in the clinical management of hay fever. Since the pioneer studies of Scheppegrell and Durham, a considerable store of information has been amassed. Yet, for a territory as extensive as continental United States, there are still many gaps in our knowledge. We are aware, of course, that many unpublished ob-

Received for publication, December 29, 1942.

servations have been made, but these need not concern us here. It is the purpose of this paper to evaluate the work which has been reported and on this basis to point out how and where future studies may be performed so as to have the greatest value.

The authors undertook to summarize the published data on this subject. In all, the literature yielded 166 studies of varying scope and content. A complete list of the references classified by states and including those for Canada will be found in a recent article.[1] Pollen data may be gathered in two ways: botanical or field observations, and atmospheric pollen counts. Of the recorded investigations, over one-half are based on the former approach, about one-third on the latter, and only about a score on a combination of both.

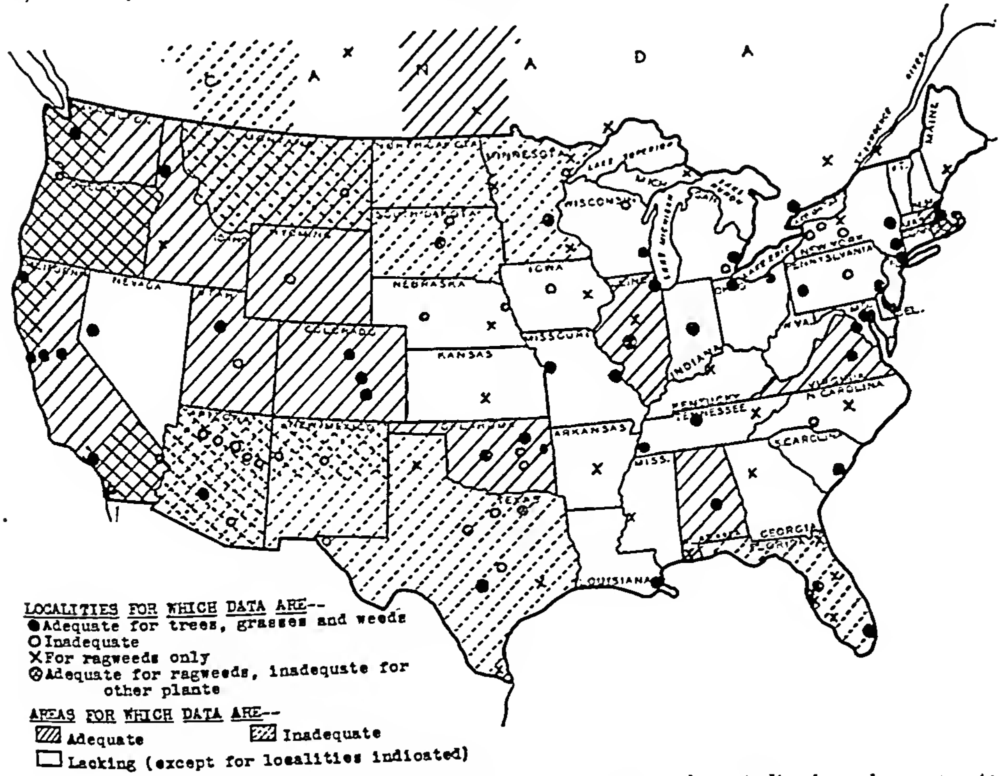

Fig. 1.—Spot map showing the localities and areas for which pollen studies have been reported. A second survey in the same region is indicated by cross-hatching.

GEOGRAPHIC CONSIDERATIONS

Pollen surveys have been reported from most sections of the United States and from some portions of Canada. Most of them concern only one city, but some include observations regarding one species made in a number of cities. Several encompass an entire state or a considerable portion of one. And a few cover several states in extent. Fig. 1 gives the exact locations and regions where such studies have been made. They are classified as inadequate if only one or a few species are considered, if over-all seasons of groups of plants are given instead of individual dates, if no dates are included, or if only a portion of the hay fever season is reported. Because so much work has been done on them

alone, the ragweed observations are indicated separately. It will be seen that, for some reason, the western portion of the country has been covered more intensively than the eastern.

The following cities, each with a population exceeding 100,000 (according to the 1940 census) have never been the scene of a pollen survey: Birmingham, Ala.; Bridgeport, Hartford, and New Haven, Conn.; Wilmington, Del.; Fort Wayne, Gary, and South Bend, Ind.; Des Moines, Iowa; Kansas City, Kan.; Fall River, Lowell, New Bedford, Somerville, and Springfield, Mass.; Flint, and Grand Rapids, Mich.; Camden, Elizabeth, Jersey City, Newark, Paterson, and Trenton, N. J.; Utica, N. Y.; Akron, Canton, Cincinnati, Columbus, Dayton, and Youngstown, Ohio; Erie, Reading, and Scranton, Pa.; Chattanooga, Tenn.; Norfolk, Va., and Tacoma, Wash. In addition, the following cities of the same size have been covered only for ragweeds: Jacksonville, Fla.; Peoria, Ill.; Wichita, Kan.; Syracuse, N. Y.; Houston, Tex.; and Spokane, Wash.

At no place in the following six states,* with a combined population of nearly nine million, have any pollination studies been carried out: Connecticut, Delaware, New Hampshire, New Jersey, Vermont, and West Virginia. If the ragweeds are disregarded, the following eight states, containing over 17½ million persons, may be added to the list: Arkansas, Georgia, Kansas, Kentucky, Maine, Mississippi, South Carolina, and Wisconsin.

Figs. 2 and 3 show directly for the ragweeds and other plants for which states information is not available or not adequate. In the evaluation here the data were considered inadequate for a state if only one city within its borders was studied, or if there was only an incomplete statewide survey. If there were studies from two or more widely separated cities within a state, or if one state wide and one city report existed, the "adequate" classification was assigned. If still more information was found, the data were listed as relatively complete.

If separate maps had been prepared for trees, grasses, and weeds other than ragweeds, the appearance of Fig. 3 would have been modified somewhat, though in the main the changes would not have been great. Table I gives the number of states falling into each subdivision for each of the major groups of plants. It will be seen that the ragweeds are by far the most widely covered, with trees the least. In addition to the states listed above, there is no information relative to the pollination dates of trees anywhere in Louisiana, Nebraska, North Dakota, Pennsylvania, and South Dakota; of grasses in Iowa, Nebraska, and North Carolina; and of weeds other than ragweeds in North Carolina.

BOTANIC CONSIDERATIONS

The reports examined varied greatly in the number of species or groups of plants included. Many involve only one, the greatest emphasis being on the ragweeds. Others consider the entire hay fever season, naming from a few to over a hundred different plants. In all, 863 species in 312 different genera are mentioned in the literature (Table II). Needless to say, not all of them bear equal weight, and in fact 392 species are referred to only once each (6 among the ragweeds, 123 among the other weeds, 169 among the grasses, and 94 among the

*We are fully aware of the fallacy of applying state borders to pollen surveys. Since a number of reports are statewide in scope, however, it forms a convenient, and indeed the only comparable, basis of comparison.

trees). These are presumably unimportant plants nationally, in relation to hay fever. As might be expected, in proportion to the number of genera or species, the ragweeds have received by far the most attention. The amount of consideration given to the other plants is surprisingly uniform. It may be noted that 5,210 pollination dates are included in 166 articles, or an average of about 31 for each. In general, one report contained the dates for a number of species in one locality, or for one species in many places. Some, of course, included many more; others only a few.

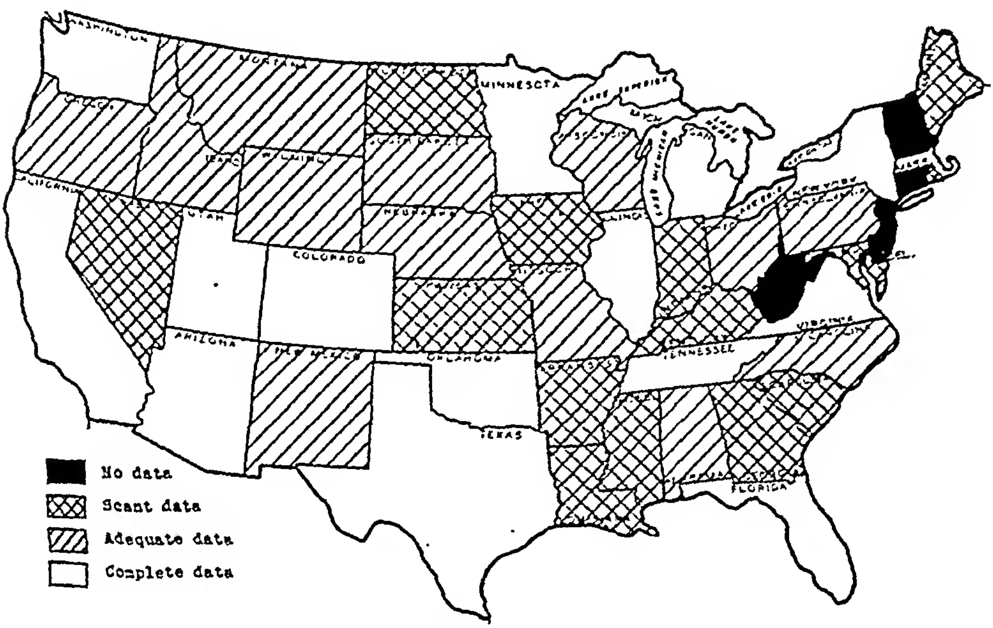

Fig. 2.—Survey of the accumulated data concerning the distribution and pollination times of the members of the ragweed family (Ambrosiaceae) by states.

TABLE I

NUMBER OF STATES WITH AND WITHOUT DATA FOR EACH GROUP OF HAY FEVER-PRODUCING PLANTS

NUMBER OF STATES	RAGWEEDS	OTHER WEEDS	GRASSES	TREES
Entirely Without Data	6	15	17	19
With Scant Data	14	14	14	9
With Adequate Data	13	9	8	10
With Fairly Complete Data	15	10	9	10

TABLE II

AVAILABLE POLLINATION DATA IN THE UNITED STATES FOR EACH GROUP OF HAY FEVER-PRODUCING PLANTS

	NUMBER OF GENERA	NUMBER OF SPECIES	NUMBER OF TIMES MENTIONED	AVERAGE NUMBER OF TIMES MENTIONED PER SPECIES
Ragweeds	4	30	748	24.9
Other Weeds	122	267	1493	5.6
Grasses	108	325	1671	5.1
Trees	78	241	1298	5.4
Total	312	863	5210	5.9

We do not for a moment maintain, either here or in the succeeding two tables, that the number of times a plant family, genus, or species is mentioned need necessarily be an index of its importance in pollinosis locally or nationally. It will be seen, however, that there is likely to be some correlation. Moreover, it is thought that these summarized statistics might be of interest in showing where the attention of the workers in this field is directed.

Table III contains a list of the most important genera, the number of species of each considered, and the total number of times each is referred to in the literature.

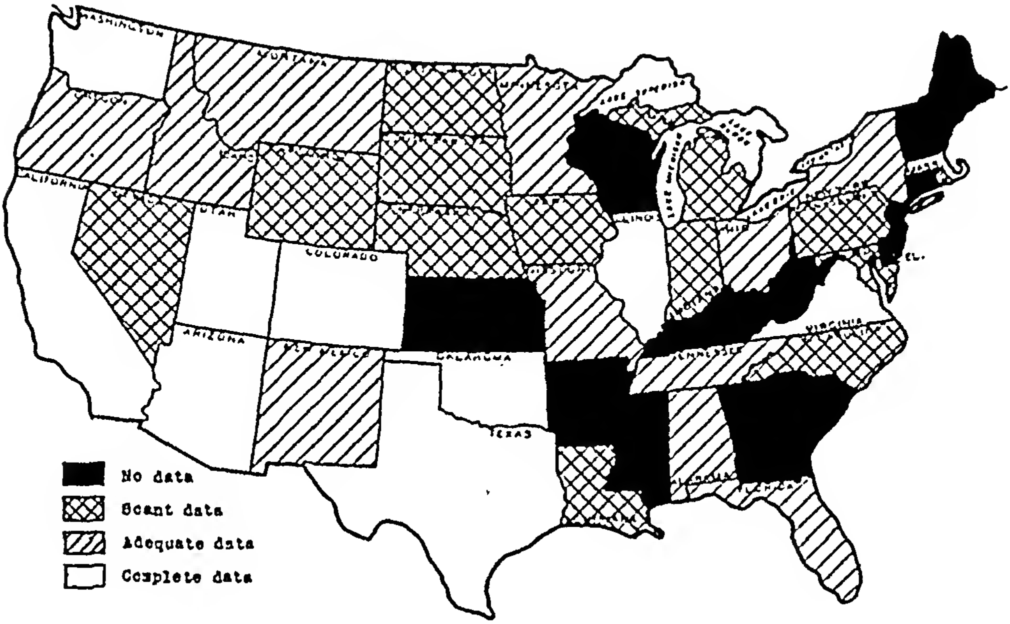

Fig. 3.—Survey of the accumulated data concerning the distribution and pollination times of trees, grasses, and weeds not members of the ragweed family, by states.

Table IV lists the individual species named most often. While notations of the "ragweeds" without differentiation of the specific representatives by far exceed all the rest, it is interesting to note that three grasses and two weeds surpass the leading ragweed. The sum of the figures for the three ragweeds included, however, reaches an impressive total. It will be seen that only four trees are to be found in the table. This is merely a reflection of the fact that many studies give dates only for the genera of trees rather than for each type, and that the statements in others are divided rather uniformly between a number of trees in each genus. Hence, few individual species were able to accumulate any considerable total.

Finally, it not infrequently occurs that a comparison of the pollination dates reported by two or more investigators for the same place reveals considerable discrepancies. For instance, the season for elm (*Ulmus*) in San Francisco is given by Rowe[2] as January and February, and by Deamer and McMinn[3] as the second week in March to the end of April; for orchard grass (*Dactylis glomerata*) in Richmond, Virginia, by Vaughan, Graham, and Crockett[4] as February 23 to June 14, by Blanton[5a] as June 6 to June 23, and by Vaughan[5b] as June

and July; and for giant ragweed (*Ambrosia trifida*) in San Antonio, Texas, by French[6] as July 29 to mid-December (first frost), and by Kahn[7] as mid-September to the end of November. Many other similar examples could be cited. These discrepancies may be explained by differences in method, by the fact that the studies were conducted in different years, or by other factors. In many instances, however, there appears no direct statement as to the techniques employed; the year in which the work was done; whether the season observed is to be taken as typical for the locality; and other pertinent information that is essential if adequate comparisons are to be made between surveys by different investigators in the same area. Variations in the stated prevalence of plants are as great or greater.

It is beyond the scope of the present paper to discuss in detail the techniques for determining pollination data. An evaluation of present knowledge, however, requires some consideration of the methods by which they are obtained. Since certain unavoidable sources of error inherent in these procedures are discussed elsewhere,[1] they need only be enumerated here. In brief, they include variations from year to year in the pollination dates of a given species, and in the relative abundance, pollinating capacity, and clinical importance of different plants, depending on meteorologic conditions; effects of the local growth of cultivated or uncultivated species over a small area; unusual conditions of exposure; and the influence of altitude on the pollination dates and nature of the flora even within a comparatimely limited region. In addition to these factors, however, there are in many studies certain deficiencies which could be rather easily controlled by a careful application of, or slight modification of, the method employed. The nature of these shortcomings and the means by which they might be overcome may best be discussed separately for each type of investigation.

BOTANICAL SURVEYS

In the first place, casual botanical surveys are of little value, since the errors of random sampling may easily affect the findings to a great degree. Only when the region under consideration is painstakingly analyzed from the botanical standpoint and an adequate number of "stations" designated, will the results be significant. Then, each station must be frequently and regularly visited, and detailed notations made of the relative frequency of each anemophilous species, the date of onset and termination of pollination, and the abundance of pollen produced. To insure that the precise dates of each important species can be recorded, the observations must be made at sufficiently short intervals. The average figures for all the stations may be considered characteristic for the area studied. Examples of investigations so performed include, among others, the surveys of Chicago by Koessler and Durham,[8] of the eastern shore of San Francisco by Rowe,[9] and of Winslow and Holbrook, Arizona, by Lamson and Watry.[10]

In this connection, it may be noted that there is no scientific justification for assuming, as many authors do, that the findings in one community are necessarily representative for the surrounding region, the state, or a considerable section of the country, unless such a conclusion is supported by observations throughout the designated area. Thus, Lamson and Watry[11] showed that four

towns in northern Arizona, although only from 42 to 66 miles apart, had very few species of plants in common. Comparable observations have been made by Sellers[12] in Texas, Mullin[13] in Colorado, and by others elsewhere.

Hickory, Pecan (Carya)	8	54
Walnut (Juglans)	5	54
Alder (Alnus)	6	42
Sycamore (Platanus)	4	36
Hazel (Corylus)	3	27

Certain deficiencies encountered in field surveys could be readily avoided. Many reports identify plants only by common names, which are often ambiguous and overlapping. Use of the technical nomenclature is far more precise and has the additional advantage of indicating botanical relationships. Some studies group considerable numbers of plants into rough seasons, such as "spring" or "fall," rather than giving the separate dates for each; others specify pollination times only by months, although greater accuracy would be desirable. The amount of consideration, if any, given to the prevalence of different plants varies tremendously, as does the explanation of the procedures by which the data are gathered.

Reference to herbarium specimens to determine the distribution and pollination times of plants, while it was of use in the early period of pollen studies, is obviously inadequate and requires no further discussion.

But even when most carefully performed and recorded, the botanical survey by its very nature must still be a comparatively crude method, particularly in estimates of the prevalence of the plants and the abundance of pollination. And even when only anemophilous species are considered, it gives no information as to how far the pollens are carried by the wind and whether they ever reach the vicinity of any considerable number of people.

TABLE IV

SPECIES MOST FREQUENTLY MENTIONED IN THE LITERATURE

SPECIES	NUMBER OF TIMES MENTIONED

POLLEN COUNTS

The pollen count or the direct determination and identification of the pollens in the air, then, is free from these two objections, since it is a quasi-quantitative measure of the actual quantity of the allergen (assuming each pollen grain of the same species to contain an equal amount) in the immediate proximity of one patient or a given population group, depending on the place of exposure. The

simplest technique merely allows the air-borne pollens to fall by gravity to the surface of a microscopic slide coated with a viscous substance, and the number caught on a fixed area (e.g., one square centimeter, one square inch, one square foot, or 1.8 square centimeters) during a unit time, usually one day, is counted and calculated. At the same time, they may be identified within the limits of the botanical differentiation of pollens by comparing them with their known characteristics[14-19] or with a reference collection of the different kinds. Needless to say, such "differential counting" of the pollens yields far more useful data than are obtained from total counts.

The morphology of the grains will vary depending on the adhesive (petrolatum, glycerin, glycerin jelly, corn, linseed, or cedar oil[20]) selected to apply to the slides. Likewise, stains (Lugol's solution, methyl green, Caberla's solution, aqueous or basic fuchsin, aqueous eosin, or nigrosin) or a contrast color method[21] may be used, if desired, to modify the microscopic appearance. Such variations in technique are at the choice of the investigator, who should, of course, be familiar with their effects. They may, in some instances, facilitate the identification, but it should be recognized that they do not in any way affect the actual findings nor lead to more minute differentiation. Recently, specially prepared slides have been suggested[22, 23] to speed the counting and to ensure accurate measurement of the surface area covered.

Various types of apparatus[24-28] have been advocated to obviate the effects of gravity. It is of interest to note that Blackley himself over sixty years ago devised an impingement method. While they have the advantage of permitting the collection of the pollen to be completed in a short period of time and thereby of detecting rapid fluctuations in the degree of atmospheric pollen pollution, they are too cumbersome for widespread practical application and provide no more information utilizable clinically than do the usual techniques. Studies based on slides exposed during airplane flights[29-32, 26] have increased our knowledge of the behavior of pollens in the upper air, but are likewise not clinically applicable.

Probably the greatest single disadvantage of the pollen-counting method is the inability to differentiate between related types of pollen grains. For example, the pollens of all the grasses are identical or nearly so. Likewise, all the members of the family Ambrosiaceae, including the various ragweeds, false ragweeds, marsh elders, and cockleburs must perforce be grouped together, as do those of the order Chenopodiales, containing the pigweed (Amaranthaceae) and goosefoot (Chenopodiaceae) families, since they are microscopically indistinguishable. This constitutes, of course, a serious obstacle to precise work in this field. It may be hoped that by means of differential stains or other techniques, a method will be developed in the future to obviate this difficulty. The pollens of the various genera of trees, on the other hand, are morphologically distinctive.

Most pollen counts have been performed in cities. Just as with field surveys, it is necessary for best results to utilize a number of carefully chosen stations, since differences of terrain, elevation, the presence of tall structures, variations in the flora of the outskirts and in prevailing winds will greatly affect the findings. Such multiple station pollen counts may be exemplified (the list being

by no means complete) by the studies of Koessler and Durham[5] in Chicago, Rowe[6] in the San Francisco Bay area, Acquarone and Gay[33] and Patterson and Gay[34] in Baltimore, and Deamer and McMinn[7] in San Francisco. There is little to be gained by emphasizing the differences between closely situated stations, but the figures for all of them may well be averaged for the community.

The intensive pollen studies by O. C. Durham in conjunction with the Weather Bureau over a number of years in many of our large cities have resulted in the accumulation of a considerable fund of information. Unfortunately, they have practically all been confined to the "ragweeds," including all members of the family, without consideration of other plants. While ragweed unquestionably is our most important plant causing pollinosis, only a small minority of fall hay fever victims are hypersensitive to its pollen alone; most of them are also allergic to other species. Moreover, in the interests of scientific accuracy, it is highly desirable to break down the family into its individual representatives in order to correlate the patients' symptoms with the pollen content of the air, to test adequately, and to treat specifically.

The authors have observed that the figures for ragweed as issued by the Weather Bureau often appear lower than the symptoms of the sufferers would seem to warrant. This is presumably due to the fact that the slides are exposed at the top of a tall building in the center of a built-up metropolitan area, an ideal place for meteorologic observations, rather than at the ground level (or more precisely, the "breathing level") in the residential sections, where the counts may be assumed to be considerably higher because of the effects of gravity and the proximity to fields and vacant lots. This illustrates the importance of choosing the sites of exposure with care, and it may be advisable, as well, to include neighboring suburban areas for similar reasons. In short, it would be advantageous to place the slides where the majority of the population spend the bulk of their day.

It has been customary in most of the reports to give graphs or tables of the daily fluctuations of the pollen counts. While this is informative, clinically it is only of minor interest in the individual case, since every sufferer and every physician is already well aware that there will be variations in the severity of the symptoms from day to day, and indeed, from hour to hour. Moreover, because the curves vary so greatly from year to year (for example, see Durham[35]), the experience of previous seasons cannot be expected to hold in the future. Hence, these quantitative considerations are of little value as compared with the simple knowledge of the species of pollen present and the exact beginning and end of the pollination of each.

The gravity method has been criticized as giving no real measure of the number, or weight, of pollen grains per unit volume of air, since each species of pollen falls at a different rate. Various formulas have been devised to obtain a volumetric value by applying to the pollen counts correction factors based on the size and shape of the grains, as well as on the surface irregularities of those which are echinated, winged, or sculptured. Scheppegrell[36] first made such an attempt based on Stokes' formula. Errors in his application of the physical principles were discovered by Cocke,[37] and mistakes in the calculations of the latter were pointed out by Dahl and Ellis.[38] The last-mentioned and

Durham[39] have also emphasized the equal significance of variations in the weight and specific gravity. There have been some differences of opinion (Cocke,[27, 32] Durham,[39] Hawes, Small, and Miller,[28] and Dahl and Ellis[38]) as to the advantage or disadvantage of employing mathematical correction factors so as to obtain a more accurate index of the number of pollen grains contained in a unit volume of air. Without entering into the merits of the various claims, one may point out that the entire question is more of academic than of practical import. Sufficient difficulties are encountered in the formulas involving size alone, disregarding the fact that pollen grains of the same species vary somewhat in diameter. But in regard to the effect of spiculation (as with ragweed pollen) or other irregularities of contour on the rate of fall, and hence on the volumetric computations, only rough estimates rather than reliable calculations are available. The same statement holds for differences in specific gravity. With any one species, the twenty-four-hour "gravity count" is an adequate guide to daily fluctuations and to comparisons of the pollen density at one locality with that at another. Furthermore, there is so much variation in the antigenicity of different pollens and in the respective tolerance of individual patients that a comparison of the relative numbers of the various species, even if perfectly accurate, would have no clinical significance. Moreover, it has been amply demonstrated that the inequalities in the counts at two or more locations within the same city, indeed, on different floors of the same building (Wilmer and Cobe[40]), may be far greater than the effect of such corrections. Vaughan,[41] in discussing the attempts at the standardization of pollen counting, concluded that for practical purposes, including comparison of the concentrations in different years, it is sufficient to record the number of grains per unit area, rather than to estimate mathematically the number per cubic yard per twenty-four hours. Certainly, none of the more recent studies gives any reason to abandon this viewpoint. Finally, while the greatest possible exactness in all aspects of this subject is desirable, simple but reliable data on the duration of pollination would far outweigh all quantitative statistics, whether on a volumetric or a unit area basis.

COMMENT

On the basis of the facts given above, what recommendations can be made concerning the most effective means of increasing our knowledge of phenologic phenomena as they relate to hay fever? It must be apparent that neither field studies nor pollen counts alone are adequate. Both must be simultaneously performed at numerous, carefully chosen stations in the given city or region and the findings correlated. In this way, they supplement each other, so that a rise in the total grass pollen count, for example, can be properly attributed to the particular species observed to be pollinating at that time. Contrariwise, the counts act as a check on mistaken conclusions as to the abundance, profuseness of pollination, or buoyancy of the pollen of various plants, as determined by botanic observations. The identification of both plants and pollens must be accurate, and scientific names employed. The exact technique and the unit of recording of the counts are in themselves of relatively little importance, but adherence to a single unit would obviously be highly advantageous. If correction factors are used, they should be clearly stated, and the basis of the computations

given. There is little to be gained by listing every anemophilous species in a locality, since in the present state of clinical knowledge many of them are of no significance. Too much emphasis should not be placed on daily variations in the count, for, as outlined above, this information is of little practical value. The stress should rather be on the determination of the type of pollen in the vicinity of potential or actual hay fever sufferers, just when each first appears and when each can no longer be found in the air. Since the pollination season varies from year to year,[1] such studies should be continued for a number of successive years so as to accumulate information, first, as to the usual or average dates, and, second, as to the amount of variation which occurs or is likely to occur. Data of this nature are immediately useful in selecting pollens for testing and treatment, in evaluating patients' symptoms, and in planning preseasonal, coseasonal, and perennial therapy.

Rosendahl, Ellis, and Dahl[42] summarize the requisites as follows: "From a clinical standpoint, it is of importance that pollen data demonstrate the following facts: 1. The approximate time (variability is not great) at which a specific kind of pollen annually makes its appearance in the air and when it reaches clinically significant concentration. 2. The duration of the period for which clinically significant amounts are present. 3. The dates (approximate) at which the concentration drops below the level of clinical significance."

While agreeing in principle, we must point out that there is no present method of determining the clinically significant concentration of pollen. While, on a rough statistical basis, the symptoms of a large group of sufferers parallel the count for their specific pollen, the correlation is a crude one, and a considerable percentage of patients seem to run contrary, or at least independently during the season, particularly in its latter portion. There is every reason to believe that the pollen incidence capable of eliciting symptoms will vary greatly for different patients: for the same patient from time to time; for different species; and will change according to the state of the offending pollen grains (dry or moist, fresh or old).

But even the most accurate, most reliable pollen data would still leave much to be desired in our evaluation of the importance of each species in pollinosis. It is a well-known fact that a pollen may be abundant and buoyant, as for example that of pine, and still give rise to little or no hay fever. This, of course, corresponds to Thommen's[43] first postulate. Only by the simultaneous collection of pollination data and the clinical investigation of large groups of patients in the same area will any basis be reached for judgment. For this purpose, statistical studies of skin reactions suggest themselves as the most readily applicable and simplest method. But skin tests alone are inadequate, since cutaneous and clinical hypersensitiveness need not always coincide. It is now recognized that a certain proportion of pollinosis cases give positive cutaneous responses to species which elicit no other allergic manifestations in them, and even to those with which, for geographic reasons, they could never have come into contact. Skin reactions should therefore be compared with the presence or absence of symptoms during the pollinating period of the given plant. In addition, nasal and conjunctival tests may often be profitably resorted so as to confirm the reaction with that of other tissues. It is likewise well-known that

some cases will fail to react to the pollens to which they are hypersensitive. Once the diagnosis of hay fever is established in such cases, the determination of the etiologic agent will depend on careful evaluation of the entire clinical picture, with special emphasis on the patients' "seasons," fluctuations in symptomatology as related to variations in pollen pollution, the response to specific therapy, and the inadvertent elicitation of constitutional reactions with specific extract. The possible difficulties encountered in evaluating the results of tests and in establishing the etiologic diagnosis are discussed by the authors[44] elsewhere. Despite these problems, it is only by a correlation of concurrent phenologic and clinical data that any safe conclusions can be reached as to the relative importance in pollinosis of each species of tree, grass, or weed.

Where may such pollen studies most profitably be performed? If the intention is merely to fill in the existing gaps, a glance at the maps and lists included will provide the answer; however, a coordinated nationwide survey combining botanic observations, pollen counts, and clinical investigations, according to a uniform technique, would yield a mass of valuable information and go far to resolve the present confusions and contradictions in this subject. The equipment required and the cost of such a study would be negligible in comparison to the utilizable knowledge it would provide. It could most advantageously be carried out in the larger centers of population, since there the great majority of hay fever victims reside, and since only there would the necessary facilities be found, along with a sufficient number of patients, to make the clinical data significant. As mentioned, the investigation would have to be continued for a number of successive years.

Very recently the Society for the Study of Asthma and Allied Conditions[45] published a preliminary record of the pollen surveys by their members. This is, indeed, the first collective effort to solve the problem under consideration, and will, when all data are published, undoubtedly prove a major contribution to the aim outlined above.

While the actual work in a study such as the one suggested could be done by allergists and botanists in the various communities, obviously a nationwide organization would be necessary to lay down standards, to decide on a uniform technique, and above all, to analyze and correlate the accumulated data so as to reach clinically useful conclusions. The logical choice for this purpose would be one of the national allergy societies or the Public Health Service.

SUMMARY

A review of the existing fund of information regarding the distribution and pollination times of the pollinosis-producing plants in the United States reveals: (1) many states and large cities where no data or only inadequate data are available; (2) certain unavoidable sources of error in the methods of investigation; (3) common correctable deficiencies in the published reports which greatly diminish their value; (4) an unwarranted emphasis, in some instances, on large numbers of species, rather than on those of clinical importance; and (5) an emphasis on quantitative considerations unjustified by present clinical knowledge or applicability.

A correlated pollen survey based on simultaneous botanical observations, pollen counts, and clinical investigations is suggested. This should be done on a nationwide scale and according to a uniform technique.

RELATION OF LENGTH OF CARBON CHAIN TO THE PRIMARY AND FUNCTIONAL TOXICITIES OF ALCOHOLS*

HENRY WELCH, PH.D., AND GLENN G. SLOCUM, PH.D., WASHINGTON, D. C.

IN A previous publication[1] a method was described for determining the toxicity of antiseptics on human or guinea pig blood as a tissue by measuring inhibition of phagocytic activity. Later work[2] showed that in many instances the phagocytic inhibition occurred through destruction of some component or components of the humoral system, while in others the leucocyte itself was destroyed. Following a study[3] of the use of other components of the blood as a measure of toxicity, a new test was described[4] in which toxicity was measured by actual death of the cell (leucocyte). Both of these tests were developed primarily to determine the direct toxic effect, mainly of antiseptics, on whole blood as a tissue. Such tests may be used to determine the "primary toxicity" of a single compound or the "relative primary toxicities" of a group of compounds.

The term toxicity has come to have a broad meaning. It is used to describe not only primary "irritating," "damaging," or "destructive" action on an isolated tissue, as used for instance by Salle et al.[5] in his toxicity test on chick embryo tissue or by Bronfenbrenner et al.[6] with his toxicity method using mouse liver cells, but also is used to designate what might be called the "functional" toxicity of a chemical injected into or fed animals in the assay of such compounds. *Hence Macht[7] describes the "toxicity" of the primary alcohols* for cats when injected intravenously, while Woodard and his collaborators[8] report on the "acute oral toxicity" of acetic and the chloracetic acids. *In contrast to the "primary toxicity" of a compound on tissue cells in vitro which measures*

*From the U. S. Food and Drug Administration, Washington, D. C.
Received for publication, January 7, 1943.

a single isolated toxic action, measurement of "functional" toxicity not only encompasses the sum of the primary toxic effects, but also includes other factors such as the selective affinity of some chemicals for certain organs, cells, or cellular mechanisms of the animal body and the physiologic effects of end products of metabolism of the chemical. Thus where "primary" toxicity is tested on human blood in vitro, using inhibition of phagocytic activity as an index of toxic effect, phagocytosis ceases in the presence of 5 per cent of methyl alcohol. Yet when methyl alcohol is taken into the digestive tract, products probably produced by intermediate oxidation bring about a deleterious effect in the animal which bear no relation to the "primary" toxic effect measured on individual cells. Similarly potassium cyanide which produces death when injected or fed in small amounts has very little effect on the isolated white cell even in high concentrations.

In the present study the primary toxicities of the monohydroxy aliphatic alcohols and the toxicities of acetic, mono-, di-, and trichloracetic acids have been determined by the method previously described,[1] using inhibition of phagocytosis in whole human and rat blood in vitro as an index of toxic effect. These toxicities have been compared with the acute oral toxicities obtained on the acids by Woodard, Lange, Nelson, and Calvery[8] and on the alcohols by Woodard.[*] The rats used were predominantly males and were raised by the Division of Pharmacology of the Food and Drug Administration. They ranged in weight from 150 to 250 Gm. and in age from 70 to 100 days. The alcohols were administered to the rats orally after an eighteen-hour fasting period by means of a soft rubber catheter attached to a syringe. Following treatment the rats were observed for six days, and those surviving were not used in subsequent experiments.

The results obtained in testing the resistance of both human and rat leucocytes to the toxic action of seven normal alcohols and the acute oral toxicity for rats of these same alcohols are given in Table I. It will be noted that as the molecular weight of the alcohols increases, the concentration of the alcohol necessary to bring about complete inhibition of phagocytosis decreases. Whereas methyl alcohol inhibited phagocytosis in a dilution of 1:20, ethyl alcohol prevented phagocytosis in a dilution of 1:30, propyl at 1:70, butyl at 1:175, amyl at 1:450, hexyl at 1:1000, and heptyl at 1:2500. The human and rat leucocyte both showed approximately the same resistance to the toxic action of the alcohols throughout the series. It will also be noted (Table I) that the molarity of the toxic dilution decreases from M/.64 for methyl alcohol to M/290.7 for heptyl alcohol in a fairly regular sequence. When the toxic molar concentration of ethyl alcohol is taken as unity and the relationship of the other six alcohols computed, it will be noted that the toxicity in this homologous series of alcohols for the leucocytes of humans or rats increases in the order of molecular weights following semiquantitatively the geometric progression described by Kamm[9] for these alcohols, $1:3^1:3^2:3^3:3^4:3^5$.

This generalization, i.e., that toxicity in a homologous series increases with the molecular weight, known as Richardson's Rule, has been verified by Morgan and Cooper[10] and by Tilley and Schaffer[11] in testing the germicidal action of

*The authors are indebted to Geoffrey Woodard for the unpublished data on the acute oral toxicities of the primary alcohols in rats.

the aliphatic alcohols, by Macht (loc. cit.) in a study of the acute toxicity of these alcohols when injected intravenously in cats and by Kamm (loc. cit.) who tested their toxicity for paramecia as well as their albumen-coagulating power. In contrast to these results when acute oral toxicity is determined in rats (Table I), there is no regular relationship between toxicity and molecular weight. The alcohols increase in functional toxicity irregularly from methyl through butyl alcohol and then decrease in toxicity from amyl to heptyl alcohol. These results emphasize the essential difference between "primary" and "functional" toxicity. In the case of the latter, the fate of the animal is determined by a variety of factors including the solubility, rate of absorption and excretion, and the effect of body fluids on the alcohol.

TABLE I

TOXICITY OF PRIMARY ALCOHOLS

ALCOHOL	TOXICITY AS MEASURED BY INHIBITION OF PHAGOCYTOSIS IN WHOLE BLOOD*			ACUTE ORAL TOXICITY IN RATS†
	TOXIC DILUTION	MOLARITY OF TOXIC DILUTION	RATIO MOLARITY TOX. DIL. TO MOLARITY TOX. DIL. OF ETHYL ALCOHOL	GM. PER KG. OF BODY WEIGHT
Methyl	1:20	M/.61	.46	9.1
Ethyl	1:30	M/1.38	1.00	7.4
Propyl	1:70	M/4.21	3.05	3.3
Butyl	1:175	M/12.96	9.40	2.75
Amyl	1:450	M/39.82	28.85	3.3
Hexyl	1:1000	M/102.01	73.98	4.1
Heptyl	1:2500	M/290.7	210.76	Approx. 6.6

*Both human and rat blood were used in these tests. Equal resistance of leucocytes to the toxic effect of these alcohols was demonstrated.

†Acute oral toxicity was determined by Geoffrey Woodard, Division of Pharmacology, U. S. Food and Drug Administration.

In order to demonstrate further the difference between what has been designated in this report as "primary" toxicity for an isolated tissue or cell and "functional" toxicity, a study has been made of acetic acid and the chloracetic acids in the same manner as the alcohols were investigated. The ability of acetic acid and the chloracetic acids to inhibit phagocytosis completely in whole human and rat blood has been determined in both acid and neutral solutions, and these results compared with the acute oral toxicity in rats as determined by Woodard et al. (loc. cit.). The results are shown in Table II, in which it will be noted that acetic acid is the most toxic and monochloracetic, dichloracetic and trichloracetic acids decrease in toxicity in that order for both human and rat leucocytes. The rat leucocyte is more susceptible to the action of these chemicals than the human. The pH of the toxic dilution decreases from 3.18 for acetic acid to 1.73 for trichloracetic acid with human cells and from 3.23 to 1.85 with rat cells indicating that the toxicity is probably related to the undissociated molecule rather than to the acidity. Computation of the molarity of the toxic dilution of all four acids, i.e., that dilution causing complete inhibition of phagocytosis, indicates that within experimental error all of these acids are toxic in equimolecular concentrations.

Since it was advisable to determine the acute oral toxicities of the acid radicals and not their toxicities as acids, the acids were neutralized with sodium

hydroxide to a pH range between 6 and 7. Neutral solutions of this type were also tested for their primary toxicity for both human and rat leucocytes. These results are also given in Table II where it will be noted that the same dilution (1:70) of all four neutralized acids inhibited phagocytosis of the human leucocyte, while a 1:100 dilution of each acid prevented phagocytosis by the rat leucocyte. In direct contrast to the equivalent primary toxicities of these four neutral acids for the rat white cell, are the results obtained on feeding these acids to rats, since it will be noted that monochloracetic acid is by far the most toxic, dichloracetic the least toxic, while acetic and trichloracetic have approximately equal "functional" toxicities.

TABLE II

TOXICITY OF ACETIC AND CHLORACETIC ACIDS

ACID	HUMAN BLOOD				RAT BLOOD				RATS
	ACID SOLUTIONS			NEUTRAL SOLUTIONS	ACID SOLUTIONS			NEUTRAL SOLUTIONS	NEUTRAL SOLUTIONS
	TOXIC DILUTION	PH TOXIC DILUTION	MOLARITY TOXIC DILUTION	TOXIC DILUTION	TOXIC DILUTION	PH TOXIC DILUTION	MOLARITY TOXIC DILUTION	TOXIC DILUTION	*ACUTE ORAL TOXICITY IN GM./KG. OF BODY WEIGHT
Acetic	1:550	3.18	.03	1:70	1:700	3.23	.024	1:100	3.31
Monochloracetic	1:400	2.27	.026	1:70	1:650	2.46	.016	1:100	.0762
Dichloracetic	1:300	1.77	.026	1:70	1:400	2.00	.019	1:100	4.48
Trichloracetic	1:250	1.73	.025	1:70	1:300	1.85	.020	1:100	3.32

*Values obtained by the Division of Pharmacology, U. S. Food and Drug Administration. J. Indust. Hyg. & Toxicol. 23: No. 2, 1941.

COMMENT

The method described previously[1] for measuring the toxicity of antiseptics or other chemicals brought into direct contact with tissue, i.e., by determining that concentration of the compound under test which completely inhibits phagocytosis, may be considered to be an estimation of "primary" toxicity on an isolated cell. This toxic action may manifest itself by a destructive effect on some component or components of the humoral system or by actual destruction of the cell itself.[4] In either case the toxic action measured is on an isolated individual tissue cell. When the primary aliphatic alcohols are tested by this technique, a definite and uniform increase in toxicity is observed with increase in molecular weight. These results are in accord with those of Kamm (loc. cit.), who found the toxicity of the alcohols for paramecia to be in proportion to their molecular weight, while similar results were obtained by Tilley and Schaffer (loc. cit.) in determining the destructive action of these alcohols for *Eberthella typhosa* and *Staphylococcus aureus*. From these studies with leucocytes, protozoa, and bacteria, it is evident that when the normal alcohols are tested for their primary toxicity for individual cells, a definite relationship between molecular weight and toxic activity can be readily demonstrated.

Similarly Macht (loc. cit.) demonstrated an increase in acute toxicity with increase in molecular weight when these alcohols were injected intravenously into cats, although the increase in toxicity with increased molecular weight does

not appear to follow a definite mathematical pattern. Thus Macht reports n-propyl alcohol to have a toxicity of 2.5 times and n-butyl 16.6 times the toxicity of ethyl alcohol. Kamm (loc. cit.) points out that the abnormalities in Macht's results for n-butyl alcohol, i.e., the fact it does not follow the geometric progression $1:3^1:3^2:3^3$, may be ascribed to a too concentrated solution of this material when injected intravenously. It may be, however, that the abnormalities noted with butyl alcohol injected intravenously into cats are associated with the method of test, and the discrepancies, an indication of the selective action of this alcohol for some vital organ. When acute oral toxicity is measured in rats, an entirely different result is obtained. The toxicities of the first four normal alcohols follow Richardson's rule, while the last three tested failed to do so. In fact, amyl, hexyl, and heptyl alcohols decreased in toxicity in that order. Undoubtedly the lower solubilities of the higher alcohols have a marked effect on oral toxicity.

When a comparison is made of the primary toxicity, i.e., toxicity for rat tissue and the acute oral toxicity of the neutralized acetic acid and chloracetic acids for rats, we again note a marked difference in the results obtained. While monochloracetic acid has an acute oral toxicity approximately 40 times that of the other three acids, the primary toxicity for rat leucocytes was found to be the same for all four acids. These results indicate that there is a marked difference between "primary" toxicity as measured by the action of a compound on an isolated tissue cell and "functional" toxicity in which the compound is fed or injected into an animal and hence influenced either by a selective affinity of the compound for some vital organ of the body or by the physiologic action of body fluids.

SUMMARY AND CONCLUSIONS

1. The primary toxicities of the monohydroxy aliphatic alcohols, acetic acid and chloracetic acids against human and rat blood as tissues have been contrasted with the acute oral toxicities of these chemicals for rats.

2. Human and rat leucocytes are equally susceptible to the primary toxic action of the alcohols, and the toxicity of the alcohols for these cells increases with molecular weight. This increase of toxicity with increase in molecular weight follows closely the geometric progression $1:3^1:3^2:3^3:3^4:3^5$ noted by Kamm.

3. The acute oral toxicity to rats of the first four primary alcohols increases with increase in molecular weight, while amyl, hexyl, and heptyl alcohols decrease in toxicity with increase in molecular weight.

4. Rat leucocytes are more susceptible than human leucocytes to the primary toxic action of acid and neutral solutions of acetic acid and the chloracetic acids. Acid solutions of the four acids were toxic for leucocytes in approximately equimolecular concentrations. Neutral solutions of the four acids were toxic for leucocytes in the same concentrations.

5. The acute oral toxicity to rats of acetic acid and the chloracetic acids bears no relation to molecular weight, since monochloracetic acid is approximately forty times more toxic than the other members of the series.

6. There is a marked difference between "primary" toxicity as measured by the direct action of a chemical on an isolated tissue cell and "functional"

toxicity as determined by the administration of the chemical where the toxic action is directed against the body as a whole.

AN UNUSUAL TEMPERATURE COURSE IN INFECTIOUS MONONUCLEOSIS*

SEYMOUR H. RINZLER, M.D., AND JULIUS J. HERTZ, M.D., NEW YORK, N. Y.

SIR WILLIAM OSLER dubbed syphilis the great mimicker of other diseases. Infectious mononucleosis with its protean manifestations is fast becoming a successful runner-up to lues in this regard. Bernstein,[1] in his excellent review of infectious mononucleosis, demonstrates that this disease may affect almost all of the body systems. Because the recording of each new manifestation of this disease will lead to its complete understanding, the report of an unusual temperature curve is presented.

REPORT OF CASE

A white male aged 25 years was first seen on the sixth day of his illness. He complained of malaise, fever, and swelling of the glands of the left side of the neck. Physical examination revealed a temperature of 101° F. and enlarged glands of the left posterior cervical chain. Excepting for later involvement of the right posterior cervical and right occipital lymph glands, the physical examination was entirely negative throughout the course of the illness. On the twelfth, fourteenth, sixteenth, eighteenth, and twenty-second evenings of the illness (Fig. 1), the patient had a sudden chill, violent enough to shake the entire bed, followed by a rapid rise in the temperature to levels between 101° F. to 104.8° F. and profuse sweating. In each instance the temperature fell by crisis within a period of two

*Received for publication, January 18, 1943.

to three hours. The chill, which lasted from ten to twenty minutes, was always preceded by an ache in the lower back which increased in intensity as the temperature rose and subsided as the temperature fell. The white blood count on the eleventh day of the illness was 7,950 with 53 per cent neutrophils (38 per cent segmented; 15 per cent nonsegmented), 40 per cent lymphocytes, and 7 per cent monocytes. The heterophile antibody reaction was negative. Two smears for malarial parasites were negative. On the thirteenth day a blood culture was negative, and agglutination reactions for typhoid "O," typhoid "H," paratyphoid "A," paratyphoid "B," proteus X19 (typhus fever), and *Brucella abortus* were negative in all dilutions. On the fifteenth day of the illness, the heterophile antibody reaction was positive in a dilution of 1:64. The white blood count was 14,700 with 28 per cent neutrophils (24 per cent segmented; 4 per cent nonsegmented), 1 per cent eosinophiles, 51 per cent small lymphocytes, 18 per cent pathologic lymphocytes, and 2 per cent monocytes. The presence of these pathologic lymphocytes, which were described by Downey and McKinlay,[2] is characteristic of infectious mononucleosis. Several urinalyses were negative. After the chill and fever of the twenty-second day, the temperature fell to normal and remained there. The patient made an uneventful recovery.

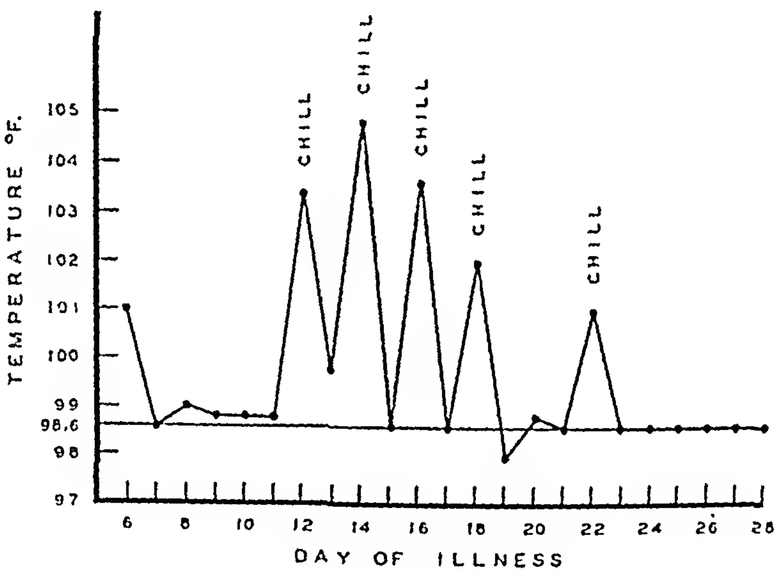

Fig. 1.—Each point represents the highest temperature for that particular day.

COMMENT

Bernstein,[1] in whose monograph on infectious mononucleosis the literature to 1940 is reviewed, does not mention such a temperature course. He further states[3] that in his personal experience he has never seen this disease behave in this way. Anyone who has dealt with the problems in the differential diagnosis of this disease may readily understand our difficulties until the true nature of the illness revealed itself. Our first clinical impressions included infectious mononucleosis, but the heterophile antibody reaction was still negative on the eleventh day. Then the series of chills and fever began. The possibility of malarial infestation was ruled out by two negative blood smears for the presence of the parasites. Sepsis and the enteric fevers were eliminated by the negative blood culture and agglutination tests. The lymphadenopathy and lymphocytosis brought to mind the possibilities of either an acute lymphatic leucemia or an acute Hodgkin's disease. The diagnosis was finally established by the positive

heterophile antibody reaction in a dilution of 1:64 and the presence of the abnormal lymphocytes[2, 4] in the blood smear. Whether or not suppuration or the breaking down of the retroperitoneal lymph glands was the cause of both the temperature response and the backache could only be surmised.

SUMMARY

A case of infectious mononucleosis with an unusual temperature course resembling that of malaria is presented. The absence of any previous mention in the literature of such a temperature response is noted.

ATTEMPTS TO OBTAIN BETTER RESULTS WITH THE BACTERIAL ANTIGEN ("VACCINE") THERAPY OF LOW GRADE CHRONIC ("FOCAL") INFECTION

I. POSSIBLE ERRORS OF USUAL METHODS

MERRITT H. STILES, M.D., F.A.C.P.* CONRAD BERENS, M.D., F.A.C.S.,† WILLIAM B. RAWLS, M.D., F.A.C.P.,‡ and GEORGE H. CHAPMAN,§
NEW YORK, N. Y.

DURING the past seventeen years we and our associates have been making a careful study of the problem of low grade chronic ("focal") infection in an effort to determine its significance. Such a study included investigation of the field of bacterial antigen ("vaccine") therapy and has resulted in the development of diagnostic and therapeutic bacteriologic methods which we believe are superior to others we have tried. This series of reports presents a discussion of the progress achieved so far.

Although most physicians believe that there is little merit in the "vaccine" therapy of low grade chronic infections, its continued use by some suggests that it must have value. Differences of opinion as to its value might be based on differences in the technique of preparing and administering the "vaccines." That there may be room for improvement in manufacture, even in standardized vaccines that have been used extensively for a long time, is indicated by the re-

Received for publication, January 26, 1943.

cent radical change in the type of organism used in the preparation of typhoid vaccine.[1] Our findings indicate that the failure to secure results in bacterial antigen therapy of chronic low grade infections may be caused by: selecting cultures that are incapable of inciting the production of suitable antibodies or of suitable quantities of them; improperly treating the cultures; failing to provide adequate surgical and supportive measures; and using unsatisfactory dosage with respect to both the interval and dose. More specifically, the following factors may have a profound effect on the course of such treatment.

POSSIBLE BACTERIOLOGIC ERRORS

a. *Culture of unsuitable foci.*—In the search for possible foci of infection a significant focus may be overlooked and cultures may be made of other foci. For example, in a patient with chronic prostatitis and rheumatism the prostate was considered the obvious focus, but only nonpathogenic organisms were found in the prostatic fluid. Highly pathogenic organisms were found in the nasal and oral cavities, which were the seat of long-standing but almost asymptomatic infection. Quite often special attention is paid to one particular focus, while others may be ignored.

If, as seems reasonable on the basis of available data,[2] "*Streptococcus viridans*" is the common denominator of low grade chronic infections, then knowledge of the incidence of pathogenic types of this organism should prove useful in indicating their most likely sources. Ruggier and Chapman[3] found resistant (i.e., probably pathogenic) streptococci to comprise 72 per cent of streptococci from periapical pockets, 54 per cent of those from extracted teeth, 44 per cent of those from the pharynx, 35 per cent of those from the nasopharynx, and 28 per cent of those found in the feces ("enterococci" being ignored). By use of an improved technique pathogenic types of streptococci were found in the pharynx in *every* person with low grade infection. For this reason the pharynx (and any periapical pockets or extracted teeth), should be cultured in every case. (The most common source of pathogenic staphylococci is the nasal cavity, which likewise should be cultured routinely.) Additional cultures should be taken from other sources whenever there is suspicion of active infection. For example, in one patient there were only 200,000 pathogenic type streptococci (18 per cent of the total streptococci in the swab) in a swab from the pharynx, but there were 5,000,000 (36 per cent of those in the gingival swab) in a swab from the gum margins, many of which showed evidence of inflammation. (See also Ruggier and Chapman.[3])

b. *Use of improper cultural methods.*—Laboratories that are infrequently called upon to make cultural studies of focal infection have difficulty in maintaining a supply of suitable culture media. Hence some of them use the Loeffler medium slants, supplied by departments of health, which are frequently dry and unsatisfactory for this type of work. Others use "blood agar" plates of varying composition, poured so thin, or which are so old, that they are dry and unsuitable for adequate growth of pathogenic bacteria, many of which require abundant moisture. Usually the material is spread on only one plate, resulting in a crowded growth that makes the study of individual colonies difficult.

Unless appropriate cultural methods are used, streptococci, particularly anaerobic types, pneumococci, some members of the Hemophilus group, and other

fastidious organisms may not be recovered. Much tedious work can be eliminated by using the newer selective isolation methods. Penicillin, recently discussed by Chain et al.,[4] and Abraham et al.,[5] is useful in the selective isolation of the Hemophilus group. Bromthymol blue lactose agar and phenol red mannitol agar[6, 7] give superior results in the selective isolation of probable pathogenic staphylococci. Crystal violet, sodium azide, tryptose blood agar[8, 23] is of considerable assistance in isolating pathogenic streptococci from mixed cultures.

c. *Taxonomic errors and unsuitable taxonomic considerations.*—Often an organism diagnosed as "hemolytic streptococcus" may be a hemolytic member of the Hemophilus group, a hemolytic staphylococcus, or even an α- or γ-hemolytic streptococcus. The presence of a small hemolytic colony on the *surface* of "blood agar" does not warrant a diagnosis of "hemolytic streptococcus." Similarly, a mucoid colony of staphylococci or of streptococci is sometimes mistaken for *Klebsiella pneumoniae*. Organisms received as "staphylococci" were found to be "enterococci" and *Neisseria catarrhalis*, and a "Type IV pneumococcus" proved to be *Streptococcus salivarius*.

Sometimes an organism is designated by an insignificant property. For example, numerous publications refer to "hemolytic" staphylococci but it has been shown[9] that the power of staphylococci to produce hemolytic zones on blood agar has only secondary significance.

d. *Error of random selection of colonies.*—When colonies are selected at random from a mixed culture they may not be representative of apparently similar colonies elsewhere on the plate. Only rarely in this type of work do we deal with cultures in which all the cells have similar properties. Therefore, in selecting a colony at random, even from an apparently pure culture, it is possible to select one that does not represent the entire culture.

e. *Influence of the age of the culture.*—Most bacteriologists harvest a culture after "overnight" incubation, an interval which may include extremes of sixteen and thirty hours. Such differences in age are often accompanied by differences in properties of the cultures.[10, 11] (We have found that late logarithmic cultures make more efficient antigens.) Metabolites, particularly hydrogen ions, may have an unfavorable effect on bacteria and their antigens. Polysaccharides, which may be related to the specificity of a bacterial antigen, are not produced uniformly throughout the period of growth of the culture. Autolytic products, the result of prolonged incubation, may alter the antigenic complex. For these reasons, it is important to know the influence of age on the antigenic structure of different cultures.

f. *Fallacy of considering the predominant organism as the focal invader.*—Many bacteriologists in medical fields consider only the gross features of a culture and make no more than a casual inspection of the plates. The relative number of the different types of organisms is estimated on the assumption that the organisms present in largest numbers are most likely to be the focal invaders. While this is often true, the rich growth of saprophytes in many parts of the body precludes the possibility of recognizing focal bacteria on the basis of predominance.

g. *Inadequacy of methods used to differentiate etiologic bacteria from contaminants.*—Because cultures from suspected foci often contain bacteria which

have no relationship to the infection, it is important that attempts should be made to differentiate these contaminants from the organisms causing the infection.

Intradermal tests, complement fixation reactions, agglutination reactions, and qualitative bacteriostatic tests have been shown to be inadequate for such differentiation.[12, 13] There is no evidence that organisms showing specific localization produce better antigens than do those not localizing in particular tissues.

Our researches[17] indicate that differentiation between causative organisms and contaminants can be made by methods based on the probability that bacteria causing infection are more likely than are contaminants to possess properties associated with pathogenicity. (It is possible that strains of low pathogenicity may be responsible for infections in tissues having low resistance; but such instances are uncommon and only a mild infection usually results.) Because of the difficulty of applying animal inoculation tests, studies were made of in vitro properties. It was found that certain of these properties were parallel with pathogenicity for animals,[7, 14, 17] were parallel with other findings[7, 9, 16, 17, 23] in the patients from whom they had been isolated, and, because they were easily reproducible, were suitable for studying large numbers of cultures.

h. *Selection of a nonpathogenic variant.*—Even though accurate methods are used to differentiate pathogenic from nonpathogenic strains, the culture selected may still be nonpathogenic because pathogenic cultures often contain nonpathogenic variants. If different colonies are tested separately, an apparently pure culture will be found in many cases to consist of a mixture of dissociants (or variants) in which different properties may be distributed in different patterns among the different cells of the culture.[3] Because this phenomenon occurs so frequently in α- and γ-hemolytic streptococci, cultures of these organisms should be considered, not as stable homogeneous masses, but as dynamic mixtures of cells with a strong tendency to instability of the biochemical, physiologic, immunologic, and pathogenic properties of the different cells of the cultures. To be fully representative, a culture must not only be genetically related to the etiologic (pathogenic) culture but must also possess its pathogenic properties.

Not much attention appears to have been paid to the possibility that the antigenic structure of a culture may change along with the dissociation of other characters. If the colony or colonies selected for preparing the growth for the antigen should lack any of the antigenic properties of the parent culture, then the antibodies produced from injection of this antigen may be qualitatively and quantitatively different from those necessary to neutralize the antigenic complex produced by the invading microorganisms.

LACK OF SPECIFICITY OF THE ANTIGEN

Even though considerable care is exercised in selecting the culture, there is still a possibility that the antigen prepared from it may not be efficient for the following reasons:

a. *There may be loss or degeneration of the antigenic properties during cultivation of the microorganism.*—Any degeneration of the culture during growth is likely to be associated with degeneration of the antigenic complex. Therefore,

steps should be taken to minimize degeneration by preventing excessive variations in hydrogen-ion concentration and excessive oxygenation, and by harvesting the culture as quickly as possible.

b. *Physical or chemical changes may be produced in the antigen after the culture has been harvested.*—Heat so injures many bacterial antigens that it is necessary to inject several million bacteria to produce a physiologic effect. In our experience 0.5 per cent phenol does not impair the immunogenic properties of staphylococci, streptococci, and Klebsiella, and does not appear to be injurious to the patients in the dosages used. Only rarely do we find sensitivity to phenol. With properly prepared antigens a physiologic effect may be produced with amounts representing less than a single bacterial cell. The antigens should be stored in resistant glass bottles to minimize the accumulation of alkali.

The essential property of a bacterial antigen is that it should be an efficient antibody-stimulating preparation. If the concentration of specific antigen should be too small (as in heated or nonspecific vaccines), the dose required to provoke a high titer of antibodies will contain so much protein that the protein itself may produce local or even general reactions.

UNSUITABLE METHODS OF VACCINE ADMINISTRATION

a. *Fallacy of attempts to force the patient to produce a high titer of antibodies.*—The usual aim in vaccine therapy is to force the patient to produce large amounts of antibodies. For this reason most schedules call for the administration of progressively larger doses to the limit of tolerance, even though the immediate results should be unfavorable. Not only is an unfavorable effect ignored, but quite often it is considered a favorable sign, an indication that the vaccine is having an effect on the patient.

On the contrary, such an unfavorable effect, if more than transitory, usually indicates that the patient is unable to produce a sufficient quantity of antibodies to neutralize the antigen. Consequently the excess antigen acts as a toxin. Recovery might be possible if sufficient opportunity were given for the tissues to produce more antibodies, but often the patient is made worse by another injection before he has had a chance to recover. When an injection is given too soon after the previous one it augments the residual antigen, resulting in even greater toxicity.

b. *Use of empirical methods for determining dosage.*—Because the laws governing response to the introduction of an antigen into the body are poorly understood and because of the difficulty in determining the precise effects, it is customary in administering antigens to follow a fixed schedule such as is suggested by manufacturers of biologic products. While such a procedure works satisfactorily in the prophylactic immunization of healthy persons (e.g., against typhoid), it is not reasonable to expect that it would work equally well in immunizing body tissues against an organism with which they are already infected. The varying amounts of antigen produced by the pathogenic organisms present, the varying damage done to tissues by these organisms, as well as the varying effects of nutritional and endocrine deficiencies, combine to alter the ability of the body to respond to the introduction of additional antigen. In our experience best results have been obtained by adjusting the dosage (i.e., both the dose and

the interval) according to the response to each injection of antigen. This subject, including our methods of estimating response to antigen injections, will be discussed in a later paper.

c. *Improper spacing of injections.*—The response to an injection of antigen is a function of the properties of the antigen, which are constant, and of the tissue reactability and antibody concentration, which vary with the interval. Therefore, it is important to space the injections to take advantage of these variations. If an antigen injection is given too soon after a previous injection, enough unneutralized antigen may still remain in the tissues to make the amount being injected too large. If given too late, the antibody level may have dropped to such a low level that several injections may be required to overcome this slump and obtain optimum response.

d. *Errors in the size of the dose of antigen.*—An inadequate dose of antigen will have only weak power of stimulating the production of antibodies. The closer a dose is to the optimum, the greater will be the degree of stimulation. However, maximum stimulation comes only from a quantity of antigen which is close to an overdose. Consequently, considerable care must be exercised when a particular dose produces marked stimulation, because a slightly higher dose, or the same dose repeated too soon, may cause unfavorable symptoms.

At times, following the administration of a dose which is considerably too large, the signs of overdosage may not be dramatic and may be mistaken for failure to respond to the antigen injection. Even if such a dose is repeated several times, the evidence of overdosage may be difficult to detect. We have seen a number of patients, usually of low vitality, who showed no evident change, either beneficial or otherwise, during a series of antigen injections, but who improved after an interval of several weeks without injections. Later these patients responded satisfactorily to smaller doses of antigen.

During an acute illness, or shortly after surgical removal or treatment of foci of infection, there is often so much circulating toxin that even minute amounts of antigen act as overdoses. Consequently, great care must be taken in giving injections in such cases. In general, it is advisable to postpone antigen therapy until a week after any acute illness has subsided, or until the immediate unfavorable effects of a surgical procedure have disappeared and improvement is evident.

In the early stages of treatment favorable response to the injection of antigen follows a curve: increasing improvement, followed by gradual return to the basic level. An injection of antigen will produce better results if it is given at the end of the period of improvement rather than after complete return to the basic level. When the immunity has been raised to a satisfactory level, the antigen may be given in rapidly increasing doses at frequent intervals.

INADEQUATE SUPPORTIVE MEASURES

a. *Failure to reduce the toxic load.*—Response to the injection of an antigen depends not only on considerations of the antigen but also on tissue reactability, which in turn is affected by the toxic load on the system. An undrained (i.e., confined) focus of infection is a source of toxic material. When the focus is

drained or removed much of this is eliminated, lightening the toxic load on the body. This is one of the most important phases of bacterial antigen therapy. In many instances in which the patient is sensitive to extremely small doses of antigen it will be found that there is an untreated focus. Numerous patients who reacted badly to small doses of antigen had a beneficial response to much larger doses of the same antigen after foci of infection had been drained or removed.

The toxic load may also be reduced by appropriate chemotherapy and physiotherapy.

b. *Failure to correct endocrine dysfunction.*—A lowered basal metabolic rate has been reported as a common finding in chronic arthritis[18] and in chronic low grade infections.[19] In patients who become drowsy after a dose of antigen that is higher than the optimum amount, the drowsiness may often be reduced by giving adequate amounts of thyroid preparations simultaneously with the vaccine injection. In patients with more definite evidence of thyroid hypofunction the continued use of thyroid preparations may prove markedly beneficial. Often, in these cases, thyroid function improves as the general health improves, and thyroid therapy may eventually be discontinued.[20]

Sex gland and adrenal deficiencies may also require attention.

c. *Failure to correct liver dysfunction.*—Liver dysfunction is common in arthritis[21] and other forms of low grade chronic illness.[22] Dietary adjustment (low fat and cholesterol, high carbohydrate and high protein) and the administration of bile salts are useful in correcting liver disturbances and in improving the response to vaccine therapy.

d. *Failure to supply adequate nutrition.*—It is generally recognized that resistance to infection is dependent to a certain extent upon nutritional factors. Dramatic response is sometimes noted when an adequate diet is supplied, or even when a single specific dietary factor is administered. The beneficial effects of the appropriate use of vitamin B complex have been especially noteworthy.

With careful attention to the details enumerated and by application of the principles to be discussed in the following papers, we believe it possible to obtain better results in the bacteriologic investigation and treatment of low grade chronic infections than are possible by other methods that have been proposed for this purpose.

SUMMARY

An analysis of some of the factors that might prevent optimum response to the bacterial antigen ("vaccine") therapy of low grade chronic ("focal") infections reveals the following possibilities:

The cultures may be taken from unsuitable foci. The recovery of organisms of suitable antigenicity may not always coincide with clinical expectations.

The cultural procedure may be inadequate from the standpoint of the technique of isolation, the method of selecting the colonies, the incubation period, taxonomic considerations, and the methods used to differentiate the etiologic bacteria from contaminants.

The culture selected may not possess suitable antigenic properties. The antigen may be injured during the cultivation process or in the later manipula-

tion. The injured antigen may contain an excessive ratio of protein to specific antigen, causing it to be toxic and nonspecific.

The dosage may be unsuitable. The injections may be given too often or the amounts may be too large. In other instances the doses may be too small for adequate stimulation of antibodies. The use of a fixed schedule is condemned.

The condition of the patient may not be favorable for optimum antibody response because of endocrine or nutritional deficiencies, liver dysfunction, an excessive toxic load (e.g., an untreated focus), or other factors.

TREATMENT OF EXPERIMENTALLY INDUCED TYPE I PNEUMOCOCCUS PNEUMONIA IN ALBINO RATS*

A COMPARATIVE STUDY OF THE THERAPEUTIC EFFICIENCY OF VARIOUS SULFONAMIDES AND SPECIFIC RABBIT ANTIPNEUMOCOCCUS SERUM AND COMBINATIONS OF THE TWO

ELMER H. LOUGHLIN, M.D., RICHARD H. BENNETT, M.D.,
MARY E. FLANAGAN, B.S., AND SAMUEL H. SPITZ, M.D.,
BROOKLYN, N. Y.

GROSS and Cooper,[1] in 1937, treated Type I pneumococcal infections in rats with sulfanilamide and rabbit antipneumococcal serum. They found that sulfanilamide was better than serum, and that when the two were combined they were more effective than either therapy alone.

In 1939, Kepl and Gunn[2] similarly treated Type I pneumococcal infections in rats with sulfapyridine and specific rabbit serum. They concluded that when serum was begun within four hours after inoculation, the combined use of serum and sulfapyridine proved more effectual than when either was used alone. When infection was well established, however, serum was more efficacious than sulfapyridine, and at this stage the combination of serum and sulfapyridine produced results no better than when serum was given alone.

In 1940, Wright and Gunn[3] reported on the treatment of experimental Type III lobar pneumonia in rats with sulfapyridine and serum. Their results differed somewhat from those of Kepl and Gunn. Wright and Gunn found that, when the infecting dose of Type III pneumococci was relatively small, serum and sulfapyridine were equally efficient, but that when the infecting dose was large, producing a mortality rate of 100 per cent in control animals, the mortality rates with sulfapyridine were lower than those obtained with serum. A combination of serum and sulfapyridine did not reduce the mortality below that obtained with sulfapyridine alone.

In each of these studies the animals were inoculated intrabronchially with pneumococci suspended in gastric mucin. None, however, report on blood cultures prior to and during treatment of the animals, making it difficult therefore to evaluate accurately the effectiveness of the therapy used, except from a standpoint of gross mortality rates. The lack of reports on the results of blood

cultures makes it impossible to determine how rapidly the therapy was able to dispose of the bacteremic state in those animals which survived.

In 1941,[4] we reported a study of the comparative efficacy of sulfapyridine and rabbit serum when used alone and in combination in treating artificially induced Type I pneumococcal infections in albino rats. We found that in these infections, which, during the animal's life, were manifested by positive blood cultures, type specific serum appeared to be more potent than sulfapyridine alone; whereas, a combination of sulfapyridine and serum, at approximately one-half the dose of either used separately, gave results similar to those obtained with serum alone.

The present report concerns a similar study made to determine the comparative effectiveness of other sulfonamide drugs when used alone or combined with specific antipneumococcal serum in the treatment of Type I pneumococcal infection in albino rats. The sulfonamide drugs employed were sulfathiazole, sodium sulfathiazole, sulfadiazine, sodium sulfadiazine, and dimethyl sulfadiazine. The last-mentioned drug, although used effectively in the treatment of pneumococcal pneumonia in human beings during the past year in England under the name of sulfamethazine,[5] is new to the field of chemotherapy in this country.

METHODS

Inoculation of the rats was accomplished by spraying small amounts of a pneumococcal culture into both the pharynx and nares, a method described in a previous paper.[6] The culture, which was suspended in 15 c.c. of a physiologic solution of sodium chloride, consisted of the washings of the peritoneal cavity of a white mouse infected with Type I pneumococci (R1 strain), and contained, as a result of the peritoneal inflammation, natural mucin in addition to the other components of an inflammatory exudate. The procedure used to inoculate the animals was entirely nontraumatizing, and, we believe, simulated the manner in which human pneumococcal infections occur.

A total of 137 rats, weighing approximately 300 grams each, were thus inoculated. Of these, 125 animals (91 per cent) became infected as manifested by blood cultures positive for Type I pneumococci. Only those animals developing positive blood cultures were used in this study.

Cultures of the blood were made just prior to the initial treatment, at 24 hours after inoculation, and at 48 hours, and 72 hours, just prior to succeeding treatments. They were then made at daily intervals until death ensued or until no growth was obtained. The blood for culture was plated on Avery's medium for pneumococci, to which was added 5.0 mg. per 100 c.c. of paraminobenzoic acid.

All the animals used, whether dying spontaneously before the fifteenth day or sacrificed on the fifteenth day, were autopsied.

Although 125 animals were successfully infected, 114 were included in this report, since in 11 animals the suspensions or solutions of the sulfonamide drugs were introduced accidentally into the trachea, producing immediate death. There was, therefore, an unequal distribution of animals in some of the groups.

To insure accurate dosage, the sulfonamide compounds, either suspended or dissolved in distilled water, were administered by gavage. The antipneumococcal serum was administered intraperitoneally by injection.

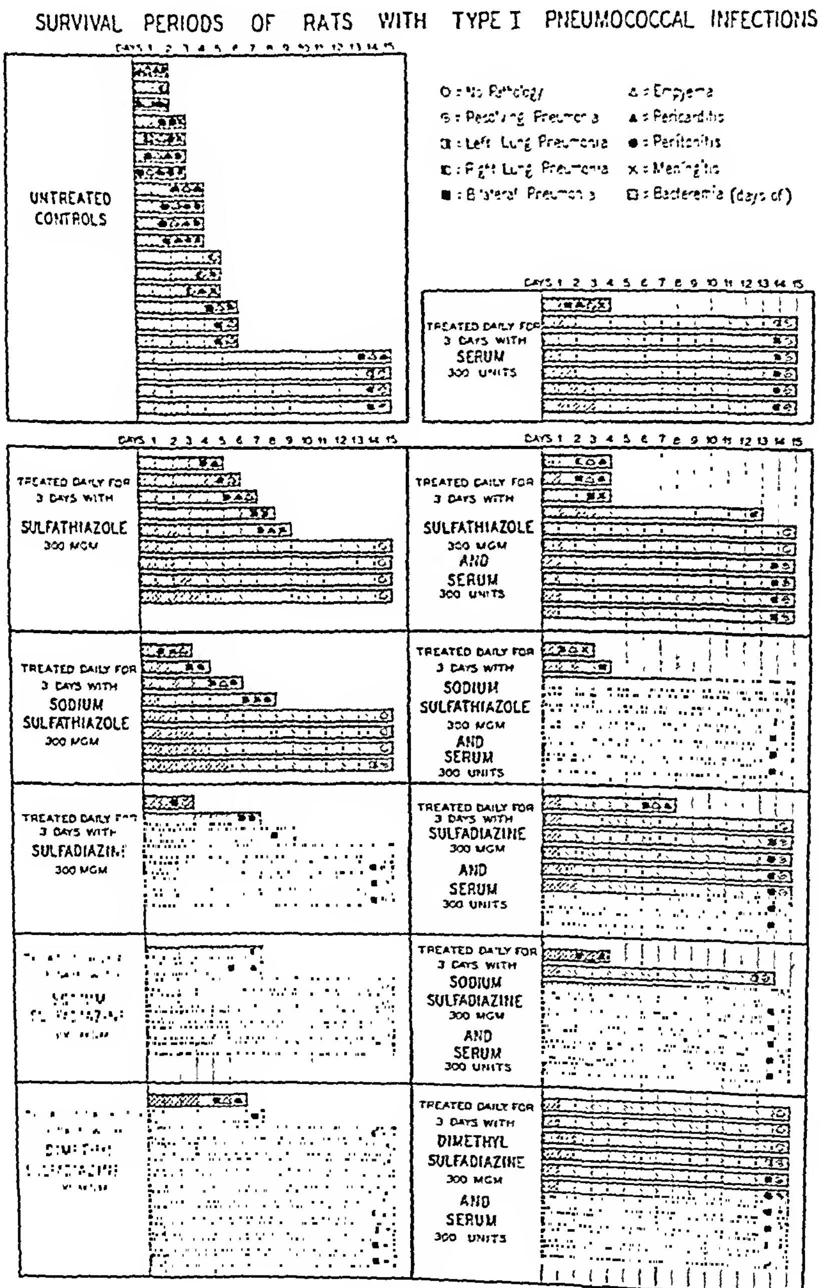

Chart I.

DOSAGE OF RABBIT ANTIPNEUMOCOCCAL SERUM AND THE SULFONAMIDES

A series of 21 animals, in which no therapy had been given, was used as a control for those receiving treatment. Therapy with serum, sulfonamides, and

combinations of the two was begun at twenty-four hours after inoculation with pneumococci.

Serum.—Three hundred units of concentrated Type I rabbit antipneumococcal serum were given on three successive days to each animal of a second series.

Sulfonamides Alone.—To a third series, 300 mg. of a sulfonamide drug per animal (sulfathiazole, sodium sulfathiazole, sulfadiazine, sodium sulfadiazine, or dimethyl sulfadiazine) was given alone to each of five groups of animals on three successive days.

Sulfonamide and Serum Combined.—A combination of 300 mg. of one of the sulfonamides and 300 units of antipneumococcal serum per animal was administered simultaneously daily for three days to each of five groups of rats of a fourth series.

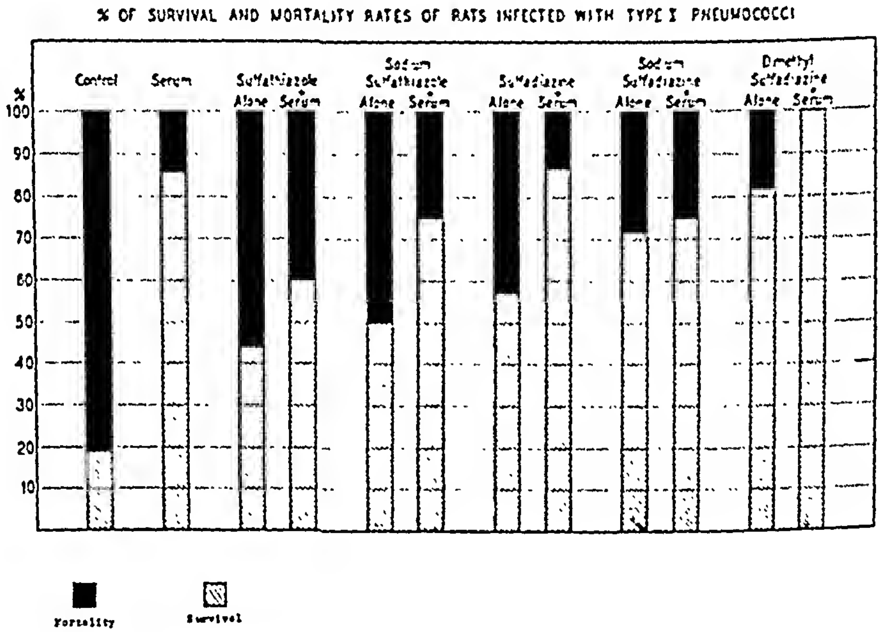

Chart II.

RESULTS

Series I, Control Animals.—Seventeen of the twenty-one rats in this series died. The mortality rate was 81 per cent. The average period of survival of those rats dying spontaneously was 3.9 days. Of these, two had pneumonia alone. Three animals had, in addition to pneumonia, one complication; four had two complications; six had three; and two had four complications. Of the four animals surviving fifteen days and sacrificed, three had resolving pneumonia, while one had bilateral pneumonia complicated by empyema and pericarditis. The average duration of bacteremia of the surviving animals was two days.

Series II, Serum Alone.—One of the seven animals in this series died, giving a mortality rate of 14.3 per cent. This rat, which died spontaneously on the fourth day, had bilateral pneumonia, complicated by empyema, pericarditis,

TABLE I

	NUMBER OF RATS			MORTALITY RATE	AVER. PERIOD OF SURVIVAL OF THOSE DYING SPONTANEOUSLY	AVER. DURATION OF BACTEREMIA OF SACRIFICED RATS
	TOTAL	SURVIVING 15 DAYS	SPONTANEOUS DEATHS	PER CENT	DAYS	DAYS
Series I—Controls	21	4	17	81.0	3.9	2.0

and meningitis. All those sacrificed had resolving pneumonic processes. The average duration of bacteremia of those sacrificed was two days.

Series III, Chemotherapy Alone.—Group "A" Sulfathiazole.—Five of nine rats died. The mortality rate was 55.6 per cent. The average period of survival of those dying spontaneously was seven days. Three had but one complication; while two had two complications. The four animals which survived for fifteen days had no pathology at autopsy. The average duration of bacteremia was three days in the sacrificed animals.

Group "B" Sodium Sulfathiazole.—Four of eight rats in this group died, the mortality rate being 50 per cent. The average period of survival of those dying spontaneously was 5.3 days. Two had pneumonia with one complication and two had two complications. Three of those sacrificed at fifteen days had no pathology, while one had resolving pneumonia. The average duration of bacteremia of the sacrificed animals was 3.5 days.

Group "C" Sulfadiazine.—Three of seven rats died. The mortality rate was 42.9 per cent. The average period of survival of those dying spontaneously was 6.3 days. Each of these animals had but one complication in addition to pneumonia. Of the four animals sacrificed on the fifteenth day, one had no pathology, while three had resolving pneumonia. The average duration of bacteremia of the sacrificed rats was 2.25 days.

Group "D" Sodium Sulfadiazine.—There were seven animals in this group. Two died; each on the seventh day, giving a mortality rate of 28.6 per cent. One had pneumonia alone; the other had pneumonia complicated by empyema and pericarditis. Four of the five animals sacrificed on the fifteenth day had no

pathology, while one had resolving pneumonia. *The average duration of bacteremia of those sacrificed was 3.4 days.*

Group "E" Dimethyl Sulfadiazine.—Of 11 animals treated, two died, one on the sixth and one on the seventh day, giving a mortality rate of 18.2 per cent; these had respectively bilateral pneumonia, empyema, and pericarditis; and bilateral pneumonia. Of the nine animals which were sacrificed on the fifteenth day, four had no pathology and five had resolving pneumonia. The average duration of bacteremia of the sacrificed animals was 1.22 days.

Series IV, Sulfonamide and Serum Combined.—Group "A" Sulfathiazole and Serum.—There were ten rats in this series. Four, or 40 per cent, died, three on the fourth day and one on the thirteenth day. The average period of survival was 5.5 days. The latter had bilateral pneumonia alone; of the other three, two had pneumonia, empyema, and pericarditis, and one had pneumonia and meningitis. Four of the six rats sacrificed on the fifteenth day had resolving pneumonia, and two had no pathology. The average duration of bacteremia of the sacrificed animals was 1.17 days.

Group "B" Sodium Sulfathiazole and Serum.—Two (25 per cent) of eight rats in this series died on the third and fourth days respectively after inoculation. The former had bilateral pneumonia, empyema, and meningitis; the latter, bilateral pneumonia. The mortality rate was 25 per cent. Of the six animals surviving fifteen days and sacrificed, two had no pathology and four had resolving pneumonia. The average duration of bacteremia of those sacrificed was 1.7 days.

Group "C" Sulfadiazine and Serum.—One of eight rats in this group died, giving a mortality rate of 12.5 per cent. This animal, which died on the eighth day, had bacteremia for one day, and at autopsy, had bilateral pneumonia, empyema, and pericarditis. The seven animals sacrificed on the fifteenth day, with one exception having no pathology, had resolving pneumonia. The average duration of bacteremia of those sacrificed was two days.

Group "D" Sodium Sulfadiazine and Serum.—Two of eight rats in this group died, the mortality rate being 25 per cent. These animals died on the fourth and fourteenth days and respectively had pneumonia, empyema, and pericarditis; and resolving pneumonia. One had no pathology. The average duration of bacteremia of those sacrificed was 2.33 days.

Group "E" Dimethyl Sulfadiazine and Serum.—Ten rats were treated and none died. All ten rats were sacrificed on the fifteenth day. Seven at autopsy had resolving pneumonia, while three had no pathology. The average duration of bacteremia was 1.6 days.

There were no instances of toxicity resulting from any of the therapeutic substances used.

SUMMARY AND CONCLUSIONS

1. Type I pneumococcal infection as manifested by positive blood cultures was produced in 114 albino rats. In those rats dying spontaneously, pneumonia, and in most instances such complications as empyema, pericarditis, peritonitis, or meningitis, were found at post-mortem examination.

2. Sulfathiazole, sodium sulfathiazole, sulfadiazine, sodium sulfadiazine, dimethyl sulfadiazine, and concentrated refined Type I rabbit antipneumococcal serum were used alone and in combination and administered to 93 animals, treatment being started at twenty-four hours after inoculation.

3. In Type I pneumonia in rats, treatment with serum alone and dimethyl sulfadiazine alone resulted in higher survival rates than with any of the other sulfonamides when used alone; whereas, a combination of serum and the sulfonamides gave better results in all instances than the respective sulfonamide used alone. Dimethyl sulfadiazine in combination with Type I serum resulted in higher survival rates than did any of the other sulfonamides. Sulfadiazine combined with serum appeared to be next in effectiveness, while sodium sulfathiazole, sodium sulfadiazine, and sulfathiazole, each combined with serum, were less effectual in this order in saving animals.

When compared with dimethyl sulfadiazine alone, sodium sulfadiazine, sulfadiazine, sodium sulfathiazole, and sulfathiazole were less effective in this order in producing survivals.

4. Sulfathiazole and sulfadiazine were more efficacious in disposing of bacteremia than were their respective sodium salts.

5. Dimethyl sulfadiazine, when used alone, cleared the blood stream of bacteremia more rapidly than any of the other sulfonamides alone, serum alone, or the sulfonamides combined with serum.

We wish to express our appreciation to Doctors Tasker Howard, Wade Oliver, and Arnold Eggerth for their careful criticisms and suggestions in this study.
We wish to thank also Mr. Sidney M. Karlton for his cooperation.

CLINICAL CHEMISTRY

SIMULTANEOUS PERFORMANCE OF WELTMANN SERUM COAGULATION TEST, CEPHALIN FLOCCULATION TEST, AND MODIFIED TAKATA-ARA REACTION AS AN AID IN THE DIFFERENTIAL DIAGNOSIS OF LIVER DISEASE*

M. WACHSTEIN, M.D., MIDDLETOWN, N. Y.

AMONG the many procedures devised for the correct diagnosis of liver diseases, those which can be performed without too much inconvenience to the patient and which can be done without too much technical difficulty are of definite advantage. Takata-Ara reaction, cephalin flocculation test, and Weltmann serum coagulation test can be performed in *one serum sample* in a fairly simple way. It is the intention of this paper to show that the simultaneous use of all three tests may be helpful in arriving at a correct differential diagnosis in a patient suffering from disease of the liver.

The Weltmann serum coagulation reaction was performed according to the original paper of Weltmann.[1, 2] The stock solution of 5 per cent calcium chloride is best prepared by dissolving 6.7 Gm. calcium chloride .2 H_2O in 100 c.c. distilled water. The final solutions which are prepared from this stock solution are numbered from one to ten. A solution 7½, containing 0.35 c.c. stock solution in 100 c.c. water, is also used. A clearly recognizable coagulation appears in the first 6 or 7 test tubes in sera from normal individuals after the test tubes containing the final dilutions of $CaCl_2$ and serum have been boiled for fifteen minutes. Under abnormal conditions, coagulation may occur in fewer than 6 test tubes, and the coagulation band, as it is called by Weltmann, is shortened or shifted to the left. Or there is coagulation in more than 7 test tubes, and the coagulation band is lengthened or shifted to the right.

Takata-Ara Reaction.—The Takata-Ara reaction was performed in the modification of Mancke and Sommer.[3] By using this method the amount of serum is kept constant, but the concentration of mercuric chloride is varied. The advantage of using this modification is the possibility of grading the reaction in a fairly simple way. No flocculation or flocculation up to the second tube constitutes a negative reaction. Flocculation up to the third or fourth tube is considered a weak positive, and flocculation beyond the fourth tube is considered a strong positive reaction.

Cephalin Flocculation Test.—The cephalin test[4, 5] was performed with the commercially obtainable Difco product. According to Mateer and co-workers,[6] this product, which is made of an especially ripened cephalin, gives reliable results. Doubtful reactions as well as weak positive ones were not regarded as positive.

---

*From the laboratories of the Elizabeth A. Horton Memorial Hospital in Middletown, N. Y., and the Beth Israel Hospital in Passaic, N. J.

Received for publication, May 28, 1943.

Fifty-two cases of primary liver disease or presenting jaundice and 70 control cases were used. The liver cases were divided into three groups: cirrhosis of the liver, diffuse hepatitis, and obstructing jaundice. Only those cases were used in which the diagnosis was reasonably certain. Cases not suffering from liver disease were used as controls.

Results.—(a) Diffuse Hepatitis.—In one of the 13 cases of diffuse hepatitis the Weltmann test showed a slight shortening of the coagulation band, in three cases a slight prolongation, and in 9 cases a marked prolongation. It is noteworthy that the most pronounced shift to the right of the coagulation band was observed in this group. (In 3 cases coagulation included dilution 9.) The Takata-Ara reaction was marked positive in 3 cases, slightly positive in one case, and negative in the remaining 9 cases. The cephalin test was positive in 7 out of 13 instances.

(b) Obstructive Jaundice.—Twenty-six cases of obstructive jaundice were examined. In 12 cases the obstruction was due to neoplasm, in 14 cases to stones. In the cases in which the obstruction was due to neoplasm, the coagulation band was in 3 cases shortened, in seven cases normal, and in only 2 cases slightly prolonged (dilution 7½). In the cases of obstructive jaundice due to stones, the Weltmann test showed in four cases a shortening and in 10 cases a normal range. The Takata-Ara reaction was one time strongly and 3 times weakly positive in the cases of obstructive jaundice due to stones; twice strongly and twice weakly positive in the neoplastic group. The cephalin test was three times positive in the stone group and twice positive in the other group, altogether 5 times in 26 cases. Erroneous results of one of the tests are frequently counterbalanced by the correcting results of the other tests. For instance, one case in this group showed a positive cephalin test, but the Takata-Ara reaction was negative and the coagulation band was shortened to 2.

(c) Cirrhosis.—In 14 cases of cirrhosis, 8 showed a marked and 2 a moderate prolongation of the coagulation band. In four cases the coagulation bands were normal. The Takata-Ara reaction was strongly positive in twelve cases, weakly positive in one case, and negative in one case. The cephalin test was 11 times positive and twice negative. In one case it was several times negative and became positive only a few weeks before the death of the patient.

Control Cases.—In 70 control cases the 3 reactions were simultaneously performed. The Takata-Ara reaction was 11 times strongly positive and 6 times weakly positive. The cephalin test was 6 times positive, once in a case of pneumonia, twice in cases of subacute bacterial endocarditis, once in a case of nephrosis, and once in a case of multiple myeloma. The results of the Weltmann test varied in different conditions. The usefulness of this test in the interpretation of various diseases has been confirmed by Teufl,[7] Levinson, Klein, and Rosenblum,[8] Levinson and Klein,[9] Dees,[10] and Kraemer.[11] Two cases of subacute bacterial endocarditis showed a lengthening of the coagulation band, a positive cephalin test, and a negative Takata-Ara reaction. These findings suggested diffuse hepatitis. There was no jaundice present, however, and there was no reason to doubt the diagnosis of subacute bacterial endocarditis on clinical and bacteriologic grounds. In one other patient suffering from cardiac failure, the results of the three tests suggested a complicating cirrhosis. The

autopsy revealed, however, only chronic congestion of the liver. In all other control cases the results of the combined tests were not misleading.

Comment.—The simultaneous use of the 3 reactions greatly enhances their value as can be recognized by critical evaluation of the tests. None of the reactions are specific. Magath[14] concludes on the basis of the literature as well as on his own extensive experience that the Takata-Ara reaction may give positive results in a wide variety of diseases. It is not a specific test but gives usually a positive result in more advanced cases of liver cirrhosis. It is frequently positive in acute hepatitis and malignant disease of the liver. The use of the cephalin flocculation test to demonstrate active disease of liver parenchyma is, without question, very valuable. We found, however, as in the Takata-Ara reaction, a number of wrong positives (8.6 per cent). A positive cephalin test might, therefore, occasionally be misleading in a patient with questionable liver disease without jaundice. The test does not always allow a differentiation between hepatogenous and obstructive jaundice. In 13 cases of hepatogenous jaundice we found the test positive only 7 times. On the other hand, the test was positive 5 times in 26 cases of obstructing jaundice. In our series the highest number of positive reactions was found in the group of liver cirrhosis. The Weltmann reaction showed the most pronounced prolongation in cases of diffuse hepatitis and also very marked prolongation in cirrhosis. It was usually normal or shortened in cases of obstructing jaundice. These findings are in full agreement with the experience of Weltmann and Sieder,[13] Teufl,[7] and Levinson and Klein.[8] The tendency to the lengthening of the coagulation band is very strongly maintained in cirrhosis especially. Complicating processes, which otherwise would lead to a marked shortening of the band, have slight, if any, influence. The coagulation band is an unspecific reaction, however, and marked lengthening is occasionally seen in other conditions.

Summary and Conclusion.—Weltmann serum coagulation band, cephalin flocculation test, and Takato-Ara reactions in the modification of Mancke and Sommer were performed. In 52 liver cases and 70 control cases it was found that by using all 3 simple tests in the same serum sample, their value for the differentiation of liver diseases could be markedly increased. Thirteen cases of diffuse hepatitis showed a frequent and pronounced prolongation of the coagulation band, a frequently positive cephalin test, and only an occasional positive Takata-Ara reaction. In 26 cases of obstructing jaundice there was found either a shortened or normal coagulation band, an occasional positive Takota-Ara reaction, and only an occasional positive cephalin test. In 14 cases of cirrhosis of the liver a prolongated coagulation band, a positive Takata-Ara reaction, and a frequently positive cephalin test were found. Only in one out of 70 control cases did the clinical picture and result of the tests lead to the erroneous diagnosis of cirrhosis of the liver.

PREPARATION AND PROPERTIES OF A DRY POWDERED MIXTURE OF SULFANILAMIDE AND HEMOSTATIC GLOBULIN*

I. A. Parfentjev, Ph.D., Mary A. Goodline, B.A., and Frances L. Clapp, B.A., Pearl River, N. Y.

About two years ago, we isolated from rabbit plasma a fraction possessing a high capacity to clot fibrinogen.[1,2] Solutions of this fraction diluted to a protein content of 10 per cent are stable and exhibit high thrombic activity. The material was preserved with 0.3 per cent phenol and phenyl mercuric acetate 1:20,000. Prepared in this way, hemostatic globulin could be Berkefeld-filtered and stored at 5° C. for over one year, at the end of which time the product showed only a slight loss of potency.[1,2]

Extensive studies on the physiologic action and clinical application of hemostatic globulin were performed by Finland and Taylor and their collaborators.[3,6,7] Additional information was presented in the paper of Bird, McSwain, Kauer, and Glenn, introduced by Reznikoff.[5] Recently Taylor and Adams extended their studies on thrombic activity of a globulin fraction prepared similarly from other species of blood (beef, swine, and human).[4] Ferguson used hemostatic globulin in the estimation of fibrinolysis.[8,9] An editorial in the *Lancet* has reviewed the work so far performed with hemostatic globulin isolated by us from rabbit plasma.[13]

During clinical trial, it was found that these preparations could be diluted to 1 per cent protein (1:10) before being used. Such dilute solutions still contained enough potency to stop, by local application, bleeding in normal persons and in hemophiliacs.[3-5] Studies on the stability of hemostatic globulin in more dilute solutions (than 10 per cent protein) and at different pH levels are now in progress.

*From the Lederle Laboratories, Inc.

Received for publication, June 23, 1943.

Recently, we prepared dry hemostatic globulin by the process (lyophilization) that is used for the drying of human plasma. This dried material was ground in a mortar and sterilized by dry heat at 110° C. for eight hours. The treatment did not affect the solubility of hemostatic globulin. Its thrombic activity was also found to be very little affected by this method of drying and sterilization. Contrary to this, solutions of clotting globulin are much more thermolabile, temperatures high enough for coagulation of proteins rapidly destroying their clotting capacity.

The next step of our research was to prepare a mixture of dry hemostatic globulin and sulfanilamide (U.S.P., 40 to 80 mesh crystals). Hemostatic globulin was added in the amount of 5 per cent to the sulfanilamide. The materials were thoroughly mixed by grinding in a mortar, and the mixture was then sterilized by dry heat at 110° C. for eight hours in small samples, not exceeding 5 Gm. Material prepared by this method was found to be sterile.

For testing the sterility of the powdered mixture, advantage was taken of the fact that bacteriostatic action of sulfa drugs is neutralized by para-aminobenzoic acid.[10-12] The usual liquid medium (Brewer's) employed for sterility tests, and suitable for both aerobic and anaerobic growth, was modified by the addition of 10 mg. per 100 c.c. para-aminobenzoic acid. To approximately 40 c.c. of this medium in Smith fermentation tubes were added by means of a sterile glass spoon approximately 50 mg. of the powdered mixture from each container tested. At least 3 per cent of the containers in each experimental lot were thus tested. The incubation period was seven days at 37° C. To check the broth for its suitability for use in sterility testing of sulfanilamide, one tube inoculated with the powdered mixture was also inoculated with pneumococci. Prompt growth of these cocci resulted upon incubation.

TABLE I

SHOWING THAT MIXTURES OF POWDERED HEMOSTATIC GLOBULIN AND POWDERED SULFANILAMIDE CAN BE STERILIZED WITH DRY HEAT WITH APPARENTLY NO LOSS OF POWDERED PROPERTY

	133H168 ORIGINAL HEMOSTATIC GLOBULIN	*26C2* MIXTURE OF SULFANILAMIDE AND HEM. GLOB. BEFORE STERILIZATION	*26C2* MIXTURE OF SULFANILAMIDE AND HEM. GLOB. AFTER STERILIZATION
DILUTIONS	DEGREE OF CLOTTING (CLOTTING TIME—5 MINUTES)		
1:10	++++	--	--
1:20	++++	--	--
1:40	++++	++++	++++
1:80	+++	+++	+++
1:160	++	++	++
1:320	±	±	±
1:640	±	±	0
1:1280	0	0	0

After sterilization the material was tested for clotting potency. The results of these tests, given in Table I, demonstrate that the thrombic activity of hemostatic globulin in the sterile sulfanilamide mixture remained unimpaired. In order to measure the thrombic activity, 105 mg. of the dry powdered mixture were suspended in 2 c.c. of physiologic saline solution, corresponding to a 1:40 dilution of original hemostatic globulin (10 per cent protein solution). From this suspension doubling dilutions were made. To 0.1 c.c. of each dilution in Wassermann tubes was added 0.9 c.c. of oxalated normal horse

plasma (0.26 per cent) preserved with 0.45 per cent phenol. The tubes were placed in a water bath at 37° C., and the degree of clotting was recorded at the end of five minutes.

In the table the column at the left records the clotting titer of the original hemostatic globulin, No. 133H168, prepared as a solution containing approximately 10 per cent protein and preserved with 0.3 per cent phenol and phenyl mercuric acetate 1:20,000. The middle column records the clotting titer of the mixture of dried hemostatic globulin (prepared from No. 133H168) and sulfanilamide, while the column at the right records the clotting titer of the same mixture after sterilization.

Clots are designated as follows:

++++	Solid clot: adheres to sides when tube is inverted.
+++	Firm clot: does not adhere to sides when tube is inverted.
++	Partial clot: flows along sides when tube is inverted.
+	Small clot: most of the material remains liquid.
±	Strands of fibrin observed when tube is shaken.

In the preceding paragraphs we have described the method of preparation of a sterile mixture of powdered sulfanilamide and hemostatic globulin. Preparation of such a mixture became possible after it was observed that dry hemostatic globulin possessed remarkable stability at high temperatures. As stated above, dry powdered hemestatic globulin withstands eight hours' heating at 110° C., and at the end of this period shows very little loss of its thrombic activity.

SUMMARY

1. Evidence is presented that dry hemostatic globulin possesses remarkable stability at high temperatures, withstanding eight hours' heating at 110° C., at the end of which period it shows very little loss of its thrombic activity.

2. The mixture of hemostatic globulin and sulfanilamide may be of value in the treatment of wounds, since it possesses both thrombic and bacteriostatic properties.

LABORATORY METHODS

GENERAL

A SIMPLE METHOD FOR THE CONSTRUCTION OF NOMOGRAPHS*

C. B. Cosby, M.A., and J. H. Weatherby, Ph.D., Richmond, Va.

FREQUENTLY it is desirable to make many rapid calculations of one general type. Nomographs have been devised for this purpose. While many ingenious ways of devising them have been offered, all depending essentially on graphic representation of logarithms, the one described here is believed to embody several distinct advantages. For other methods, as well as a general discussion of nomography, the appended bibliography may be consulted.

Nomographs are not uncommonly seen in such diverse journals as "Barron's Financial Weekly," "Educational Psychology," "Anatomical Record," and the "American Journal of Hygiene." Statisticians and actuaries use them so frequently that there is now available a "Handbook of Statistical Nomographs." Since they are a valuable tool in engineering and scientific research, a simple method for their construction would appear to be of value.

Mathematical formulas are merely expressions of addition, subtraction, multiplication, and division of variables and their constants. In Fig. 1 is shown the scheme for simple addition or subtraction of two numbers, which plan represents the fundamental device of nomography. Here scales are equally divided and evenly spaced apart. Numerical values are assigned to the scales so that any point on the middle scale has twice the value of the corresponding point on either of the other scales. For example, in the addition of 4 and 12, a line called the isopleth line, drawn from 4 on one side scale to 12 on the other side scale, crosses the middle scale at 16. To substract 4 from 16, a line is drawn from 4 on the left scale through 16 on the middle scale until it intersects the right scale, this point of intersection indicating the difference between the two numbers.

Since multiplication and division can be accomplished quite conveniently by the addition or subtraction of logarithms, this same principle can be applied to these processes. When the scales are graduated logarithmically instead of equally, the distances can be added or subtracted, giving the desired multiplication or division. For this purpose the value of any point on the middle scale is made equal to the square of the corresponding point on either of the side scales, as shown in Fig. 2. Since any selected distance on the side scales is

*From the Department of Pharmacology, Medical College of Virginia, Richmond, Va. Richmond, Va.
Received for publication, October 2, 1942.

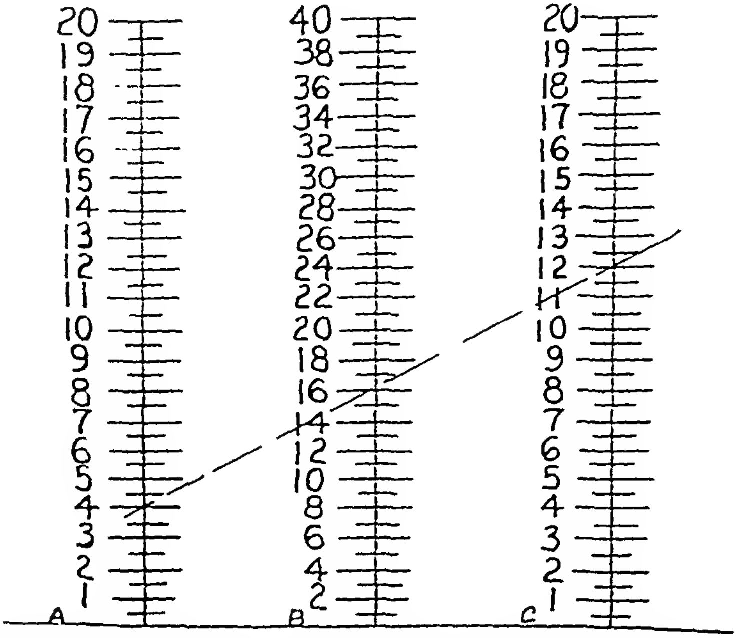

Fig. 1.—Simple nomographic addition. A + C = B, the diagonal line indicating 4 + 12 = 16 or 16 − 4 = 12.

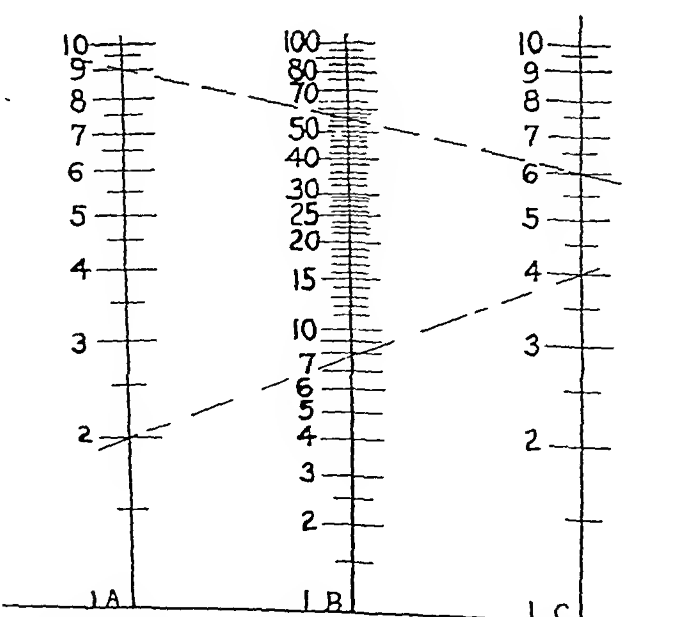

Fig. 2.—Simple multiplication, logarithmic division of scales; the product of A × C = B. As shown, the diagonal lines indicate 9 × 6 = 54 and 8 ÷ 2 = 4.

proportional to the logarithm of a number, the addition of such distances results in multiplication of the numbers. As shown, we have $9 \times 6 = 54$ and $8 \div 2 = 4$. If the side scales are not equally spaced from the middle, this displacement in itself constitutes a factor of multiplication. In the simplified system presented here intentional displacement of this kind is avoided.

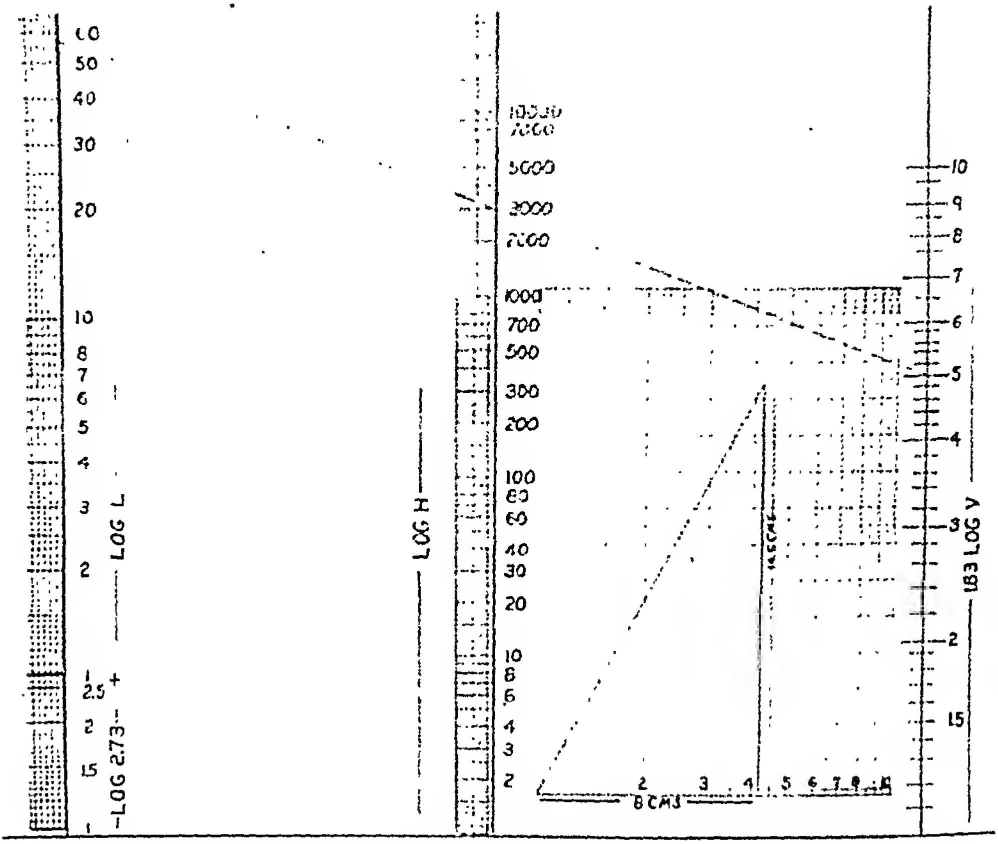

Fig. 3.—A nomograph to show $h = 2.73\ LV^{1.83}$ or $\log h = \log 2.73 + \log L + 1.83 \log V$. h = loss of head pressure in 2" pipe in ft. ÷ 1000, L = length of pipe in ft./1000 and V = velocity of liquid ft./sec.

In Fig. 3 is shown the formula and the nomograph for the calculation of the loss of pressure in a pipe in which the loss is dependent on length and velocity of the liquid passing through the pipe, $H = 2.73\ LV^{1.83}$. The novel feature here consists in the use of strips of logarithm paper held in position on stiff bristol board by cellulose tape. This obviates the laborious and tedious division of scales and also insures greater accuracy. The center scale is equally spaced between the side scales. Further, all scales begin at the same base line of value 1, so that decimals, digits, tens, etc., are easily determined. Usually logarithms are used to solve this equation; i.e., the log of $h = \log 2.73 + \log L + 1.83 \log V$. The log of 2.73 is added to the log of L by cutting a strip of log paper at 2.73, and then the regular cycles of logarithms are placed above so that 1 begins at 2.73. To obtain 1.83 log V, in the insert, 8 cm. were measured off horizontally on logarithm paper, 1.83×8 cm. vertically, and a line was drawn as shown. Each unit of length on the horizontal scale has above it a segment 1.83 times

its length. These values are transferred to the right hand scale by means of dividers. The center scale is of paper twice as finely divided as the left scale. Anyone contemplating constructing nomographs will find the several varieties of log or semilog paper available of great assistance.

In Fig. 4 is a nomograph for calculating the resistance of a parachute, in which the same system has been used. The square of V is obtained by using for the right hand scale paper that is twice as coarse as that used on the left, that is, having one cycle correspond in length to two cycles. For the center scale the paper is twice as finely divided as that used for the left scale.

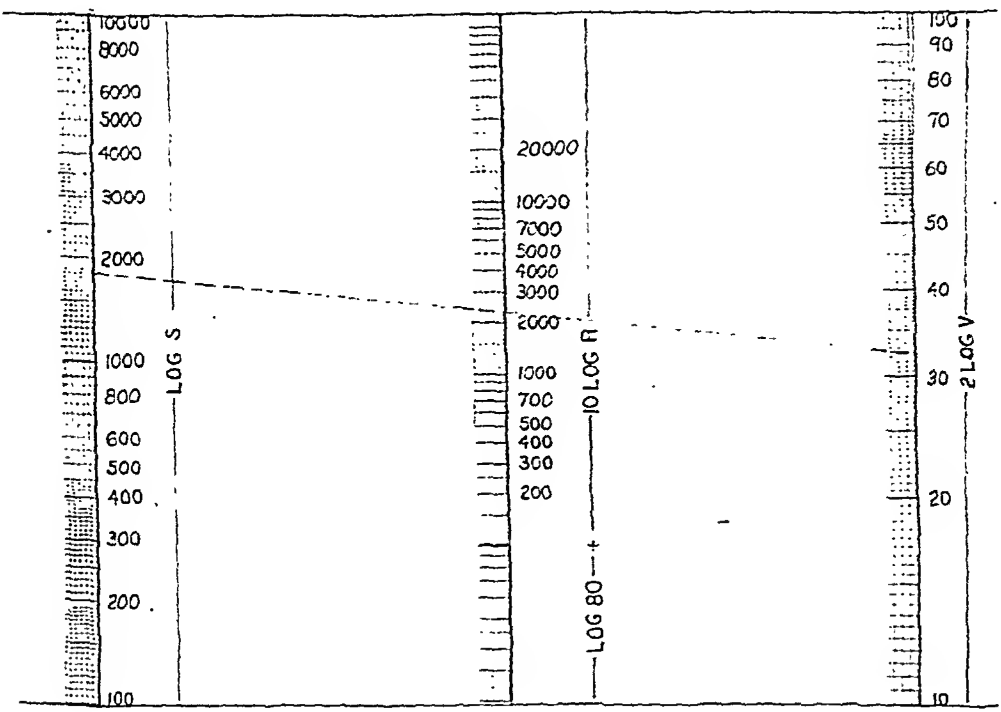

Fig. 4.—A nomograph for the resistance of a parachute as given by the formula $R = \frac{SV^2}{008}$ or 800 $R = SV^2$. R = resistance, S = area in ft.², V = velocity in ft./sec.

In Fig. 5 is shown the formula for the standardization of insulin in which there are five variables. Two variables are combined by division to obtain a reference line, this combined with a third variable to obtain a second reference line, which is left in the middle product position, and to the right is placed the C scale for division by C. Of course the constant 1.5 is taken into account by shifting A upward 1.5 logarithmic units. Finally the remaining scale gives the values of U. It should be noted that the reference lines are not divided, since their purpose is merely to give points for beginning the next operation. The value of these points as such is not needed.

The accuracy of these nomographs, just as in arithmetical multiplication, depends on the number of decimal places one keeps; that is, on logarithm paper one cycle corresponds to one decimal place. Any misplacement of the axes introduces an error. The limit of fine division varies from 25 to 100

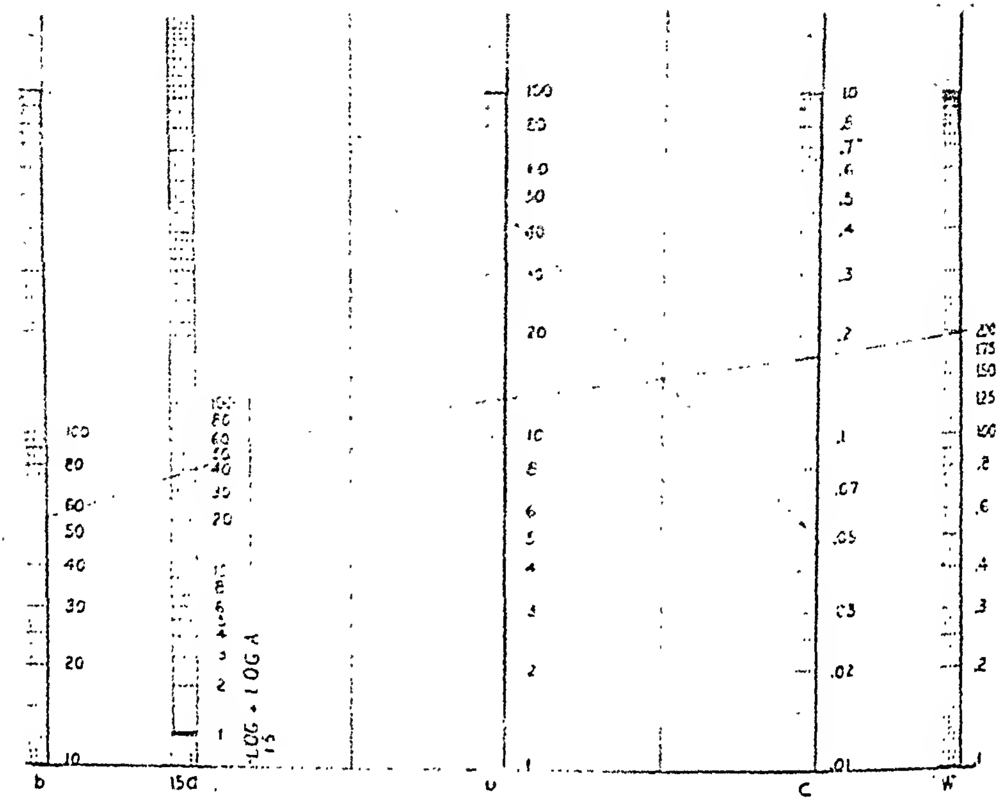

Fig. 5.—A nomograph for the standardization of insulin. $U = \frac{1.5\ AW}{bc}$, W = wt. of rabbit in kg., C = c.c. of injection, a and b, blood sugar percentages as usual in technique.

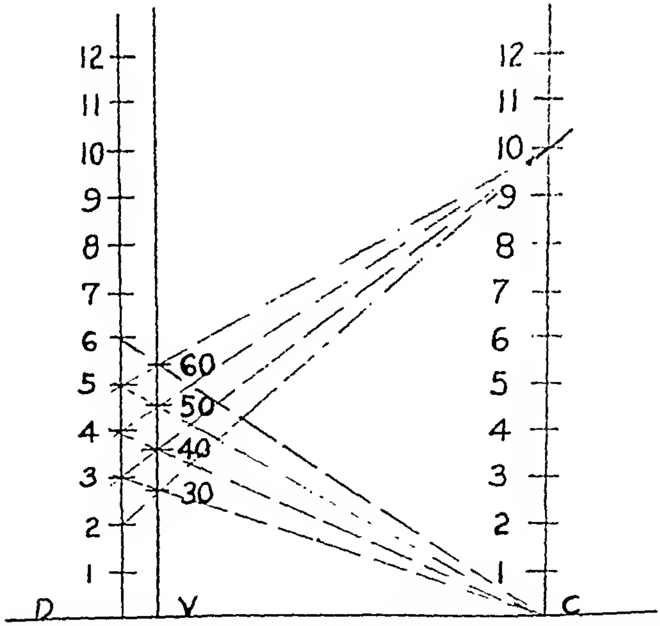

Fig. 6.—Empirical derivation of a nomogram for the simple formula V = 10 d + c, V = value in cents of a mixture of dimes and pennies, D = number of dimes, c = number of pennies.

divisions per inch, depending on the instruments used and the care exercised. Accuracy may be increased by enlarging the graph, but size ultimately reaches a conveniently usable maximum. Also, the isopleth should never slant more than 45 degrees from the horizontal, since intersections are less distinct at a greater angle. Also, it must be remembered that errors are compounded as the process is carried from scale to scale. All these may be minimized by care in construction of the nomograph, by the use of equally spaced axes when possible, having all scales begin at the same base line, and by the use of machine-ruled paper whenever possible. For permanent use and for copies, large photographs may be used under ground glass. The isopleths may then be drawn and sponged off repeatedly.

The nomographs illustrated here were selected for purposes of demonstration only, and not for specific application. While novel effects may be obtained with systems other than that employing vertical equally spaced axes, the ease and simplicity of the procedure outlined are to be recommended.

For unusual situations, such as those involving the functions of angles, recourse may be had to the empirical method as simplified in Fig. 6. Here, the result desired is the number of cents which are equivalent in value to a mixture of dimes and cents. The outer scales are evenly divided. The location of the middle scale, as well as its divisions, is determined in the following manner. Isopleths are drawn from the points zero and ten on the C scale to several points (2, 3, 4, 5) on the D scale. The intersections of the isopleths locate the position of the third scale and its divisions. The outer scales are straight vertical lines; the resulting intersections may indicate a straight line as shown in this illustration, but in other more complex relations, usually a simple curve.

TWO NEW METHODS OF STAINING VAGINAL SMEARS*

Dorothea Fuller, B.S., M.A., New York, N. Y.

During recent years great interest has developed in studies of the vaginal secretions, based on the work of Papanicolaou. From time to time new staining techniques have been devised.

In this communication two stains† are described. The first, PGI, is recommended for studying the menstrual cycle; the second, Post Graduate II, is designed for the differentiation of malignant cells.

POST GRADUATE I FOR ROUTINE SMEARS

Fix smears immediately in equal parts of 95 per cent ethyl alcohol and ether for at least five minutes.

Run down through graded alcohols (80 per cent, 50 per cent, 30 per cent) to water. Stain in Ehrlich's hematoxylin diluted one-half with distilled water for two minutes. Wash in running water for four minutes.

Stain for two minutes in I.

Rinse quickly in water.

Stain for two minutes in II.

Rinse quickly in water.

Stain for one minute in III.

Rinse quickly in water and run up through alcohols to xylol and mount in clarite or dammar.

Staining Solutions:

1. (a) 1 Gm. ponceau de xylidine.
   99 c.c. distilled water.
   1 c.c. glacial acetic acid.
   (b) 1 Gm. acid fuchsin.
   99 c.c. distilled water.
   1 c.c. glacial acetic acid.
   Mix two parts of (a) with one of (b).
2. 2 Gm. orange G.
   1 Gm. phosphomolybdic acid.
   100 c.c. distilled water.
3. 1 Gm. fast green.
   100 c.c. distilled water.

Superficial cells stain green, deep cells a slightly darker green; highly cornified cells stain orange, and the less cornified cells, pink. Red blood corpuscles, when fresh, stain pink; when old, green.

---

*From the Department of Gynecology, New York Post-Graduate Medical School and Hospital.

These studies were made possible by a grant from Mr. Jeremiah Milbank.

I wish to express my grateful appreciation to Dr. Walter Dannreuther for his constructive criticism.

†All the stains are National Aniline and Chemical Co. dyes.

Received for publication, September 29, 1942.

POST GRADUATE II FOR MALIGNANT CELLS

Fix, and run down to water, and stain in the diluted Ehrlich's hematoxylin as before.

Wash and run up through ascending alcohols (50 per cent, 80 per cent, 95 per cent).

Stain for two minutes in the following stain:

11 c.c. saturated eosin (in 95 per cent alcohol).
35 c.c. saturated orange G (in 95 per cent alcohol).
8 c.c. saturated fast green (in 95 per cent alcohol).

(In mixing this stain, add the eosin to the orange G and shake; then add the fast green slowly.)

Differentiate (agitate vigorously and rapidly) in 99 c.c. absolute alcohol with 1 c.c. glacial acetic acid in it for about one minute. Rinse in absolute alcohol to xylol and mount as before.

(This stain does not keep very long in its mixed form, and the saturated solution of orange G must be the first saturation. If the malignant cells stain too dark, add a few more c.c. of orange G.)

Superficial cells stain green, the cornified cells, red, and the malignant cells are usually red or purple.

These two stains have been used routinely in the endocrine clinic of the Department of Gynecology at the New York Post-Graduate Medical School and Hospital. They have shown a high degree of specificity and have proved eminently satisfactory in cell differentiation and diagnosis.

ON THE USE OF FIREPROOF COTTON IN BACTERIOLOGIC WORK*

Lillian J. Camagni, A.B., Nutley, N. J.

THE technique of testing bacteriostatic activity in vitro as carried out in this laboratory, and most likely also in other laboratories, involves the repeated flaming of the mouths of the test tubes and of their cotton plugs. It occurred frequently that by flaming, the plugs of neighboring test tubes, and occasionally a whole group of them, were set afire, thus not only causing an undesirable delay in the execution of the experiment, but also increasing the danger of secondary contamination. In order to avoid this disturbing and sometimes even dangerous occurrence, we suggested the use of fireproof cotton as closing wads for the tubes. This proved to be a considerable help in carrying out in vitro tests speedily and with a high degree of safety. We eventually replaced all ordinary cotton wads used for test tubes, flasks, and other containers by fireproof cotton. We have used the fireproof cotton for more than six months; since this modification was found to be most satisfactory, in our laboratory as well as in other laboratories of the research and production depart-

*From the Research Laboratories of Hoffmann-La Roche, Inc., Nutley, New Jersey.
Received for publication, October 13, 1942.

ments of the plant, we feel justified in recommending fireproof cotton for bacteriologic laboratory work.

Fireproof cotton shows no definite difference as compared with ordinary cotton. It stands repeated sterilization in the autoclave as well as in the hot air sterilizer. Temperatures up to 200° C. produce but a very slight browning of the fireproof plugs. Exposure to more than 200° C. or heating at 200° C. for periods longer than two hours should be avoided. The overheating produces a deep brown coloration of the plugs, which are finally disintegrated. They break easily, and a fine brown dust may cover the bottom of the glass containers.

When flamed in the flame of a Bunsen burner, fireproof plugs are only superficially charred, even if exposed for several minutes. There is no danger that the chemicals (e.g., boric acid and sodium tetraborate*) adsorbed in the process of fireproofing might exert a bactericidal or bacteriostatic activity and convey it to the medium if it inadvertently comes in contact with the plug. In order to prove this, the following experiment has been carried out repeatedly:

Sterile wads of fireproof cotton (weight 0.7 to 0.75 Gm.) were drowned in 25 c.c. papain digest broth with 0.2 per cent glucose and kept for twenty-four hours at room temperature (20° C.), in the refrigerator (45° C.), or in the incubator (37° C.). A fourth sample was boiled in the broth for five minutes. The different samples of broth were filled in test tubes, sterilized, and inoculated with typhoid bacilli, hemolytic streptococci, *Streptococcus viridans* and pneumococci Type I. After forty-eight hours' incubation, all tubes showed as normally heavy growth as the controls which had not been in contact with fireproof cotton. The organisms were not altered morphologically and grew typically in subcultures on solid medium.

Fireproof cotton is commercially available† and less expensive than adsorbent cotton. It can, moreover, be prepared in the laboratory.‡

*U. S. Patent 2,185,695.

†We used the fireproof cotton of the Lockport Cotton Batting Company, Lockport, New York.

A SIMPLIFIED SERUM DILUTION METHOD FOR THE QUANTITATIVE TITRATION OF PRECIPITINS IN A PURE ANTIGEN-ANTIBODY SYSTEM*

Donald S. Martin, M.D., Durham, N. C.

INTRODUCTION

The antigen dilution method of precipitin titration, based upon observation of the highest dilution of antigen yielding a visible precipitate in a constant serum-varying antigen series, continues to be used by many investigators, despite the demonstration by Cromwell,[1] in 1925, that an end point obtained by this procedure has no relationship to the antibody content of a serum. This point was emphasized again by Culbertson,[2] who suggested that the antigen dilution method is more applicable to the titration of antigen concentration than to the estimation of antibody content. This procedure is listed as an approved method of precipitin titration in most textbooks of bacteriology, however, and in the latest edition of an authoritative textbook of immunology.[3]

Our interest in the problem arose from a study of the optimal proportions method of precipitin titration, using a photoelectric method for recording the reaction rates of various antigen-antibody mixtures.[4] It was demonstrated that the galvanometer deflection produced by an antigen-antibody precipitate five minutes after mixing was directly proportional to the antigen concentration in the original mixture if there were sufficient antibodies to precipitate all the antigen. The deflection was not changed by any increase in antibody concentration. These observations were in complete agreement with those of Cromwell[1] and Culbertson[2] in that the smallest amount of antigen producing a visible precipitate is a function of the antigen concentration alone, excluding the antigen dilution procedure as a suitable titration method.

On the other hand, the more logical serum dilution procedure has not been used extensively, presumably because of the failure of the earlier workers to obtain precipitates with moderately diluted serum and because it was soon demonstrated that the serum and not the antigen provided the larger part of the precipitate. It seems justifiable to attribute some of the low titers obtained by investigators using the serum dilution method to their use of relatively high concentrations of antigen as the test dose, the inhibiting effects of excess antigen becoming more marked as the relative antigen-antibody ratios are increased in the mixtures containing the higher dilutions of serum.

It was felt, however, that a serum dilution method could be used for the accurate titration of precipitating antibodies if the inhibiting effect of excess antigen could be excluded by using, as a test dose, the smallest amount of antigen yielding a visible precipitate in the presence of excess antibodies.

*From the Departments of Bacteriology and Medicine, Duke University School of Medicine and Duke Hospital, Durham, N. C.

Received for publication, October 22, 1942.

EXPERIMENTAL

The Type I pneumococcic polysaccharide and the refined antipneumococcic rabbit serum (471-11-409-11) were obtained from the Lederle Laboratories through the courtesies of Dr. A. L. Joyner and Miss Frances Clapp.

Sufficient polsaccharide was dissolved in 0.85 per cent saline to make a concentration of 0.512 mg. per c.c. Progressively doubled dilutions of this stock solution were made to give a series of final antigen concentrations ranging from 0.256 mg. per c.c. to 0.0000625 mg. per c.c. after mixing with equal parts of the various serum dilutions. The progressively doubled serum dilutions, prepared in the same way, gave final concentrations ranging from 1:25 to 1:12,800.

The direct precipitin tests were performed by mixing 0.5 c.c. quantities of each reagent in Wassermann tubes. The mixtures were shaken a few times and examined for precipitate formation after standing for two hours at room temperature.

Tests for excess antigen and antibody were made on the supernatants, cleared by centrifugation after the mixtures had stood overnight in the icebox. To one-half of each supernatant was added an equal quantity of a 1:50 dilution of serum, and a solution of antigen containing 0.0085 mg. per c.c. was added to the other half.

The optimal antigen-antibody ratio, obtained by observing the antigen concentration precipitating fastest in a mixture containing a 1:100 dilution of serum, was determined by the photoelectric method.[4]

RESULTS

The results of the direct precipitation tests, presented in the upper half of Table I, are recorded as + or –, no differentiation being made as to the degree of flocculation or turbidity.

The end point in each of the "antigen dilution" titrations was the same (0.00025 mg.), although the most concentrated serum tested (1:25) contained 256 times as many antibodies as the 1:6,400 dilution. These findings were in complete agreement with those of Cromwell[1] and Culbertson,[2] and confirmed our observations obtained with the photronreflectometer.[4] The results are interpreted as eliminating the antigen dilution technique as a quantitative method for determining antibody content.

The "serum dilution" titrations, on the other hand, showed that the end points obtained with the various antigen dilutions were dependent to some extent upon the concentration of antigen used in the test. These end points would not be expected to lie in a straight line because of the well-known fact that precipitation occurs in the region of moderate antigen excess. As the concentration of the test antigen is reduced, however, the end points obtained by the serum dilution technique approach more closely to the true antibody content because of the reduction in the relative amount of excess antigen that can be precipitated by the diluted serum. Consequently it is logical to choose as the test dose of antigen the smallest concentration capable of yielding a visible precipitate with an equivalent amount or an excess of antibodies, in this instance 0.00025 mg. of polysaccharide per c.c. The highest dilution of serum precipitating this amount of antigen must therefore contain just enough antibodies to precipitate this

amount of antigen, there being no excess of precipitable antigen present in the mixture.

If the unit of antibodies be defined as the amount of antibodies equivalent to 1 μg. of antigen, as suggested by Marrack and Smith,[5] this 1:6400 dilution contained 0.25 units giving an antibody titration value of 1,600 units per c.c. of undiluted serum. The same value would have been obtained by using as test antigen the solution containing 0.0005 mg. per c.c. which reacted with the serum diluted 1:3,200. Completely misleading results would have been obtained, however, if a more concentrated test antigen had been used. For example, the antibody value of the serum, based on titration with the antigen solution containing 0.256 mg. per c.c., would have been 25,600 units per c.c., an obviously false value because this dilution of serum did not precipitate all the antigen in the mixture as shown by the presence of excess antigen in the supernatant.

\+ Precipitate
− No precipitate
A Excess antigens in supernatant
a Excess antibodies in supernatant
() Optimal ratio (fastest reacting mixture)

The results of the supernatant examinations are shown in the lower half of Table I. This portion of the table can be interpreted as a series of "neutralization point" determinations, as described by Culbertson,[2] who showed that at this point "antigen and antibody combine in a constant ratio to give the maximum precipitate obtainable from the antiserum." The neutralization method gave very accurate end points except in the highly diluted antigen and antibody mixtures in which supernatant examinations would be expected to fail because the tests for residue antigens and antibodies were made on materials already doubly diluted. As expected, these neutralization points lie in a straight line and calculation from any point in this line shows that 1 c.c. of undiluted

serum contains sufficient antibodies to completely precipitate 1.6 mg. or 1600 μg. of antigen.

With serum diluted 1:50, the fastest precipitation, measured by the photron-reflectometer, occurred when an equal amount of a solution containing 0.032 mg. polysaccharide per c.c. was added. In terms of final concentration, 0.016 mg. of antigen was optimal with 0.01 c.c. of serum, indicating again that this serum contained 1600 units of antibodies per c.c.

In order to emphasize the necessity of using the least amount of precipitable antigen as test material in the serum dilution procedure, the equivalent antigen-antibody ratios, as determined by the neutralization and optimal proportions methods, are connected by a heavy line in the upper portion of Table I.

DISCUSSION

Although the data presented in this paper were obtained with a polysaccharide antigen, there is no reason for doubting its application to the titration of other antigen-antibody systems. Cromwell[1] used sheep hemoglobin and crystalline egg albumin antigens in his experiments, and Culbertson[2] did his work with crystalline egg albumin. At present we are using this method to determine the precipitin response of rabbits to the injection of beef albumin,[6] and in other experiments, we have shown that the galvanometer deflections caused by the precipitation of sheep globulin and albumin are dependent entirely upon the antigen concentration.[7]

All of the methods commonly advocated for the titration of precipitins require the use of a series of mixtures containing constant amounts of undiluted or weakly diluted serum and varying amounts of antigen. In such a constant antibody series the various end points used for estimating the precipitin content can be classified as follows: (A) the highest dilution of antigen yielding a visible precipitate, (B) the dilution of antigen producing the greatest weight or volume of precipitate, (C) the dilution of antigen producing the fastest formation of a precipitate, (D) the highest dilution of antigen completely precipitating the antibodies as indicated by the absence of antigen and antibody in the supernatant, and (E) the determination of antibody N in the precipitate at the equivalence point.

Method A has been shown to have no relationship to the antibody content and need not be considered in spite of its continued use by some observers. Method B yields results which show some relationship to the antibody content, but the method is not quantitative since the greatest weight[8] and the greatest volume[9] of the precipitate are found in the region of antigen excess. Method C is an accurate method of titration if a photoelectric method is used to record the reaction rates in the early phases of the reaction.[4] As originally described by Dean and Webb,[5] the optimal proportions procedure lacked accuracy because these authors suggested that the optimal time for reading the reaction was at the time of beginning particulation. Since the photoelectric method is a specialized procedure requiring the use of an expensive apparatus, it is not recommended for routine use in the titration of pure antigen-antibody systems. This method, however, is the only quantitative method which is applicable to the titration of precipitins in mixtures containing more than one antigen and more than

one antibody. Method D is very satisfactory for the quantitative titration of precipitins in pure antigen-antibody systems but requires centrifugation and special care in selection of the proper dose of antigen for testing the supernatants. Method E is a highly specialized procedure requiring relatively large amounts of serum.[10] The data obtained by this method, however, have been of incalculable value in the advancement of knowledge concerning the chemical factors involved in the precipitin reaction, because the antibody content of a serum can be expressed in terms of actual weight of antibody protein.

The serum dilution procedure, described in this paper, has a distinct advantage in that the titration requires only small amounts of serum; this suggests that this method would be especially valuable in the measurement of residue antibodies in absorbed sera. It must be emphasized, however, that the serum dilution technique, like the microchemical and neutralization procedures, cannot be applied to the titration of complex antigen-antibody systems.

It is unfortunate that the popularity of the antigen dilution technique of titration has resulted in its use by many investigators who often have drawn rather far-reaching conclusions from the data obtained by this method. This point can be illustrated by examination of the data presented in a paper published by Wolfe,[11] which was selected for criticism only because of its recent publication in a leading immunologic journal. This author concluded that chickens were excellent antibody producers, because high precipitin titers could be obtained frequently by a single injection of a small amount of diluted antigen. Although this conclusion may be correct, it is not justified by the data which were obtained by the antigen dilution method. His results show that the sera contained sufficient antibodies to precipitate a minute amount of antigen but give no indication as to the degree of antibody response. The use of the antigen dilution method, however, does not explain the variations in end points obtained by this author, and at least two explanations can be offered for these discrepancies. In the first place, since complex antigens (bovine, sheep, and buffalo serum) were used for immunization and testing, a number of different specific antibodies could have been formed, each antibody being present in a different concentration. A second cause for the variations may be in the use of the rather uncertain "ring test" method of setting up the reactions. The "underlayering" of 0.5 c.c. of an antigen solution with 0.1 c.c. of serum is a rather difficult procedure and introduces the possibilities of error in the measurement of the serum and in obtaining a perfect layer between the antigen and antibody solutions.

The effect of using too concentrated antigen solutions in the serum dilution titration method can be illustrated by a paper published recently by De Gara and Bullowa.[12] These authors, in a study of antibody production in serum sickness, were able to demonstrate precipitins in only one-half of their cases and concluded that serum sickness can occur without the development of observable precipitins. Although this conclusion may be correct, it must be noted that their method was incapable of detecting precipitins unless a very high precipitin titer had been developed by the patient. Since these workers used undiluted foreign sera as antigens, it is obvious that it would take a high concentration of antibodies to overcome the inhibiting effect of these concentrated antigens and to precipitate even a fraction of the precipitable antigen.

SUMMARY AND CONCLUSIONS

A simplified serum dilution procedure is described for the quantitative titration of precipitins in a pure antigen-antibody system.

The titration values obtained by this method are in complete agreement with the values obtained by the "neutralization point" and optimal proportions methods.

The complete lack of relationship between the antibody content of a serum and the titration values obtained by the popular antigen dilution method of titration is discussed.

AN IMPROVED METHOD OF STERNAL MARROW ASPIRATION*

Joseph Litwins, M.D., New York, N. Y.

THIS communication concerns a description of an improvement in the technique of sternal marrow puncture and aspiration. The improvement consists of the localization of definite landmarks and of the use of a two-way valve either incorporated in the needle or as an adapter attached to the needles now in general use.

The routine technique employed in sternal marrow aspiration consists in puncturing the sternum below the angle of Louis, using the suprasternal notch as a midline landmark. We have found that by placing the middle finger of the free hand on the angle of Louis and the thumb and index fingers on the

*From the Metropolitan and Flower and Fifth Avenue Hospitals, Lbn J. Boyd, M.D., Director of Medicine; Louis Greenwald, M.D., in charge of Hematology.
Aided by a grant from John Wyeth and Brother.
Received for publication, October 22, 1942.

lateral borders of the sternum in the second interspace, unmistakable and immovable landmarks are obtained. The puncture is then made below the middle finger and between the thumb and index fingers. In infants, where the puncture is performed in the manubrium, the middle finger is applied to the suprasternal notch and the thumb and index fingers along the lateral borders of the manubrium.

The sternal puncture needles now in use are superior to the original ones in that they are shorter and permit a firmer grasp in the performance of the procedure; this is of value particularly when the sternal plate is rather hard. In such patients with hard sternal plates, after the marrow is aspirated, it is difficult to remove the needle and syringe simultaneously without at times breaking the tip of the syringe or losing marrow material. It is to prevent such occurrences that this method, the use of a two-way valve, is described. This permits the removal of the syringe having the needle remain in situ until after filling the white cell pipette, and making smears. The needle is then removed.

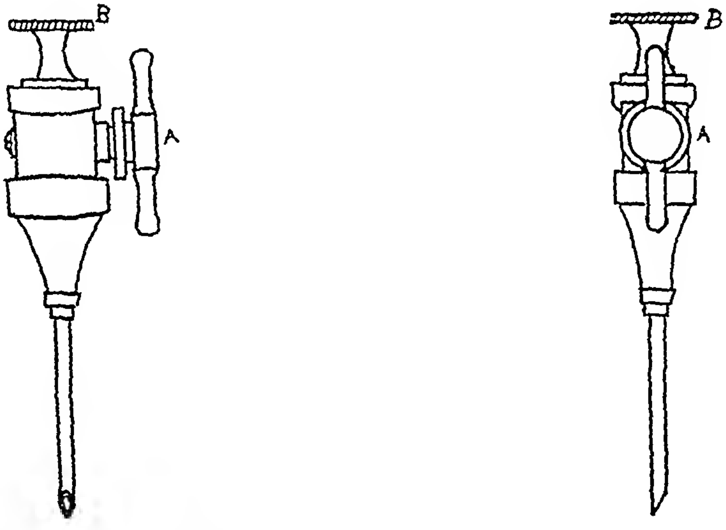

Fig. 1.—Needles used for sternal marrow aspiration. Actual size. *A*, valve control; *B*, stilet.

This may be accomplished by means of a two-way valve either as part of the needle, or as an adapter attachment. By means of the valve one may control the amount of marrow to be aspirated, since often too much marrow is sucked up, causing dilution of the marrow. Again in the so-called "dry" tap, especially in aplastic and osteosclerotic marrow after suctioning and turning off the valve, a small amount of material, sufficient to make one or two smears, may be trapped in the needle.

A three-way valve may be used for sternal transfusions, a procedure which may have to be resorted to rather often in wartime.

AN ORGAN PERFUSION PUMP*

WILLIAM KLEINBERG, ALBERT S. GORDON, AND HARRY A. CHARIPPER,
NEW YORK, N. Y.

AT THE present time increasing importance is being attached to studies dealing with circulatory phenomena in isolated organs. A detailed analysis of such problems necessitates the use of a simple, easily adaptable organ

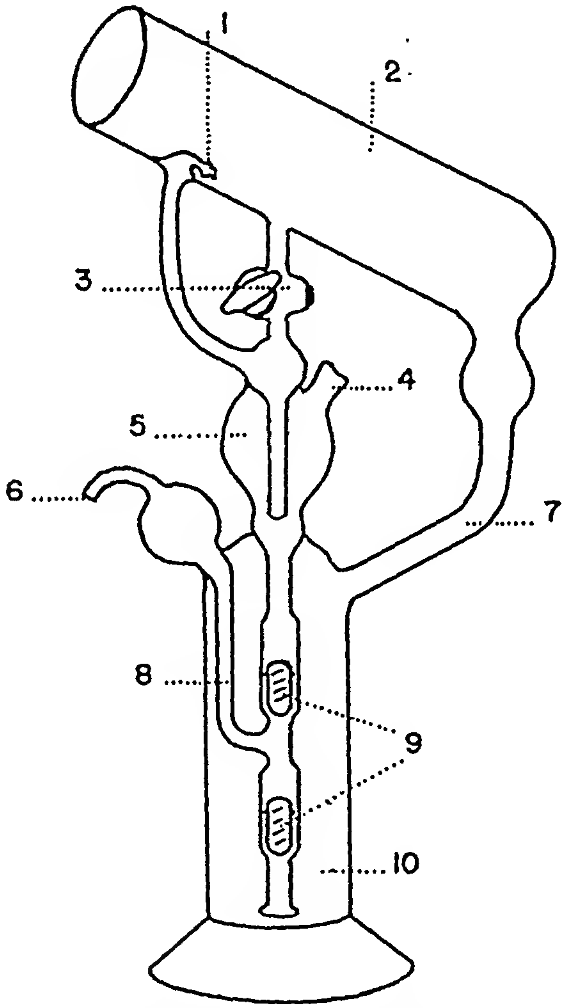

Fig. 1.—(1) cannula, (2) organ chamber, (3) by-pass, (4) outlet to pressure gauge, (5) compression chamber, (6) outlet to rubber bulb, (7) return tube, (8) pulsating fluid column, (9) gravity valves, (10) reservoir.

perfusion pump. The apparatus to be described is a single unit, made of glass and designed for sterile procedures. The mechanism is relatively inexpensive

*From the Department of Biology, Washington Square College of Arts and Science, New York University, New York.

Received for publication, October 27, 1942.

and well adapted for use in small laboratories. All necessary adjustments of systolic, diastolic, and pulse pressure, pulse rate, etc., can be made and changed at will without interrupting the continuous flow.

Perfusion fluid flow is controlled by the action of two ground-glass, gravity valves, under the influence of a pulsating fluid column interposed between the valves. A by-pass stopcock allows any amount of the perfusion fluid and all air bubbles to be shunted and gives precise regulation of pressures. If finer adjustment is desired, the stopcock can be grooved slightly so that the fluid will flow through the grooves when the cock is turned. The necessary elastic properties can be regulated by varying the amount of air in the compression chamber. A pressure gauge is connected to the outlet of this bulb. Filters (glass, silica, platinum mesh, etc.) can be inserted at any point in the return tube or at the bottom of the reservoir.

The rate and amplitude of pulsations are regulated by the rate and degree of compression of a sturdy rubber bulb by any motor mechanism. We have, for example, adapted a sewing machine head to serve this purpose. The systolic pressure is related directly to the extent to which the rubber bulb is compressed. The diastolic pressure may be altered by changing the diameter of the opening in the by-pass. Pulse pressure, therefore, can also be changed at will.

The capacities of the different parts of the pump may be modified to suit individual needs. We have found these to be satisfactory for our work: reservoir, 300 c.c.; organ chamber, 400 c.c.; and compression chamber, 50 c.c.

The blood vessel of the organ to be studied is attached to a cannula and then by a short length of gum rubber tubing to the cannula of the organ chamber. The latter cannula can be filled previously with perfusion fluid by closing the stopcock and applying the drive mechanisms for a few strokes.

The apparatus has been used successfully for studies on perfused endocrine organs, and these will be described in another paper.

THE EFFECT OF FREEZING ON ERYTHROCYTES*

Lloyd Florio, B.A., M.D., Dr. P. H., Mabel Stewart, B.S., Edward R. Mugrage, M.A., M.D., Denver, Colo.

INTRODUCTION

THE statement most commonly made by authorities on hematology is that freezing destroys the human erythrocyte. Since it seemed to us theoretically possible to preserve red blood cells by quick freezing, we were stimulated to study the responses of the erythrocyte to this procedure.

FUNDAMENTAL CONSIDERATIONS

It is possible to freeze and thaw the red blood cell with very little cellular destruction. The speed of freezing and thawing and the concentration of certain sugars added to the blood are fundamental in the preservation of the human erythrocyte by freezing.

TECHNIQUE

Most of the results to be reported were on the human erythrocyte. Blood was drawn aseptically and mixed with dry sodium citrate so that the final concentration of the anticoagulant in the blood was 0.5 per cent. The freezing mixture consisted of ethyl alcohol and solid carbon dioxide which attains a temperature of approximately –75° C. One-half c.c. of blood and 0.5 c.c. of 20 per cent glucose were placed separately into an aluminum cup, 1 mm. in thickness, which is about the size of a water glass. The blood and sugar solution was mixed just before the cup was partially immersed in the cold bath. The best results were obtained if the freezing time was between 3.5 and 5 seconds. We found 1.0 c.c. of mixed blood and glucose the ideal amount of material to work with under the conditions of our experiment. Thawing was accomplished by dipping the cup for 1.5 to 2 seconds in a water bath held at 75° C. In order to study the blood over prolonged periods of time, 1.0 c.c. amounts were frozen, thawed, and pooled. The blood in the pooled specimens was kept refrigerated at 6° C. in sterile flasks. These were allowed to reach room temperature during a one-hour period at the same time each day. The red cells were then counted and the hemoglobin determined. The same pipet and counting chamber were always employed for each sample. Hayem's diluting fluid was used. The hemoglobin was determined by the Sahli technique on the supernatant fluid from a small specimen removed from the flask. The Sahli instrument had been standardized against the Van Slyke oxygen capacity method. In the initial hemoglobin determinations, the supernatant fluid contained so little hemoglobin that the usual Sahli technique could not be used. These initial estimates of hemoglobin were arrived at by color comparisons with samples of the original blood which was hemolyzed to known concentrations of hemoglobin by the addition of distilled water. Fifty milligrams per cent of sulfathiazole was added to both the frozen and control specimens to help

*From the Department of Public Health and Laboratory Diagnosis, University of Colorado School of Medicine, Denver.

Received for publication, October 29, 1942.

maintain sterility although every attempt was made to carry out the entire procedure aseptically. Certain studies carried out by us and several reports in the literature indicate that the addition of this small amount of sulfa drug has no deleterious effect on the blood.

RESULTS ON HUMAN BLOOD

As a result of this procedure 97 to 98 per cent initial preservation was achieved in terms of hemoglobin remaining in the red blood cells and over 99 per cent preservation in terms of cells not destroyed. This may indicate a certain amount of leakage of hemoglobin without destruction of the cell. The hemoglobin concentration in the cell was definitely less than one would expect on the basis of cell count. This is illustrated in Chart I, which represents a typical pooled sample from 20 similar samples of frozen blood followed daily by red cell counts and hemoglobin determinations. The scales on the chart are constructed so that the cell count and the hemoglobin concentration are equivalent.

CHART I

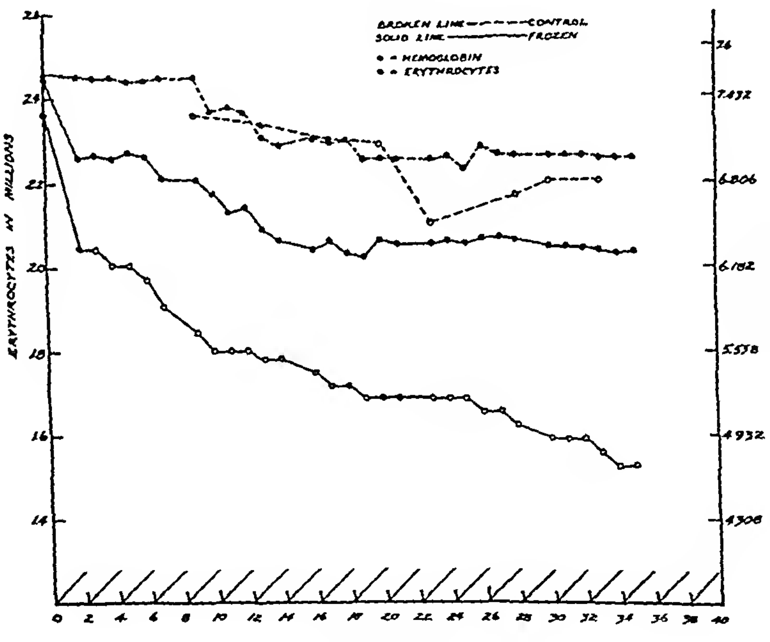

Chart I.—Pooled frozen and control specimens of human blood followed daily by red blood cell counts and hemoglobin determinations.

There was an initial fall in both the cell count and cell hemoglobin in the specimen that was frozen and thawed. After forty-eight hours this leveled off so that a moderately constant relationship was maintained in comparison with the control specimen, which differs only in not having been frozen. Microscopic study always revealed the presence of shadow cells or cells with a much reduced hemoglobin concentration. This was not found in the control.

RESULTS ON OTHER BLOOD

We have made a few studies on the blood of sheep, dogs, and rabbits. The initial results paralleled those found in human blood. The deterioration was

much more rapid, however, especially in respect to hemoglobin leakage, which took place at an accelerated rate even in the control specimen. The accompanying charts illustrate these points.

Unlike the experiments on human blood, however, no attempt has been made to work out the ideal technique for freezing and preservation of the different animal bloods. The conditions found best for the preservation of human red blood cells may not apply to any other blood.

PROPERTIES OF FROZEN BLOOD

Of the many properties of blood we have compared only a few. The oxygen-carrying capacity was unimpaired. Previously frozen cells can be typed with the same ease and accuracy as the unfrozen blood.

Studies on the fragility of the cells revealed peculiarities that depend on the glucose concentration of the specimen. The fragility decreases as the sugar concentration increases, even after the cells were thoroughly washed. Suffice it to say that the fragility of the frozen and unfrozen cells was identical within 0.02 per cent sodium chloride and significantly lower than the same blood not previously mixed with glucose. The whole subject of the fragility of red blood cells suspended in glucose requires further elucidation.

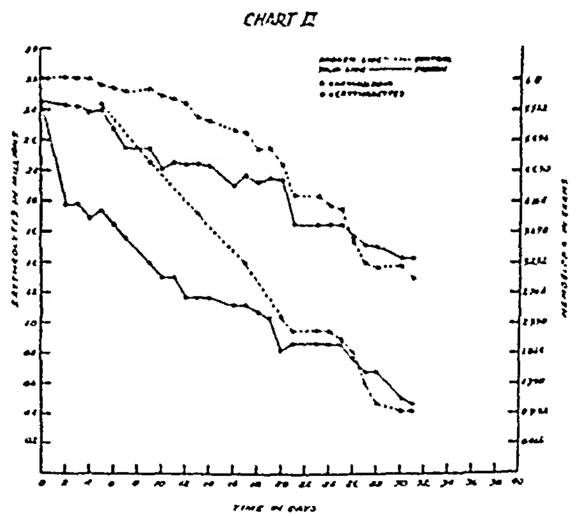

Chart II.—Pooled frozen and control specimens of dog blood followed daily by red blood cell counts and hemoglobin determinations.

Chart III.—Pooled frozen and control specimens of rabbit blood followed daily by red blood cell counts and hemoglobin determinations.

OTHER TECHNIQUES EMPLOYED

Many freezing and thawing techniques were tried but discarded, because the results were not as good as with the procedure which has been described. The blood was sprayed on solid carbon dioxide; small drops were frozen; copper and glass instead of aluminum vessels were used. Blood was also frozen in the ice compartment of an electric refrigerator at –12° C. While there was little hemolysis with this latter procedure if thawed immediately after freezing, destruction of red blood cells took place comparatively rapidly if the blood was kept frozen any length of time.

To thaw, the frozen material was added slowly to fluids of various compositions kept at temperatures ranging between 40° C. and 50° C. or allowed to melt at room temperature. This latter technique always resulted in complete hemolysis except in the case of the blood frozen in the ice compartment.

One might think that freezing of the blood more rapidly, say in one to two seconds, would give better preservation. This was tried but the results were highly unsatisfactory. A mixture of acetone and solid carbon dioxide achieves this quicker freezing. With this mixture, the blood can be frozen in 1.5 seconds. While the temperature of this mixture and our usual one of alcohol and carbon dioxide are the same, the difference in freezing time can probably be explained by the insulating effect of the carbon dioxide bubbles in the alcohol. This phenomenon of bubbling is not observed with the acetone-carbon dioxide mixture. Liquid air was also tried, but it is difficult to handle and the freezing time is about the same as with the alcohol-carbon dioxide mixture.

If we mixed 20 per cent glucose and the blood in equal amounts and allowed this mixture at least twenty-four hours to reach equilibrium before freezing, the results were never as good as when the blood and glucose were mixed within thirty seconds of freezing.

The concentration of plasma does not seem to be a vital factor in preservation. Equally good results were obtained with washed cells resuspended in glucose.

A final concentration of glucose in the blood between 9 and 11 per cent gave good results. More or less sugar resulted in a larger cell destruction on freezing. We routinely employed a 10 per cent final glucose concentration. Galactose, fructose, and sucrose gave less satisfactory results.

While several anticoagulants were quite satisfactory, we consistently used sodium citrate because it is cheap and easy to make up in the desired concentration.

STORAGE AND DRYING IN THE FROZEN STATE

Red blood cells frozen at –75° C. and stored at –12° C. for one hour in the ice compartment of an electric refrigerator invariably are completely hemolyzed on rapid thawing. We have made some attempts to determine the critical temperature at which cells are destroyed. Our experiments suggest that temperatures higher than about –40° C. result in a hemolysis of the erythrocytes. Storage of the blood in a frozen state at the temperature of solid carbon dioxide indicated that there is no deterioration during the first three days of storage. Technical difficulties have made the studies over longer periods inaccurate, but the results to date indicate a slow deterioration in the frozen state from the third to the sixteenth day.

Our few attempts to dry the cells from the frozen state on the cryochem apparatus always resulted in failure. While it is possible to preserve the cell structure when the blood is converted back to a liquid, the cells were practically completely devoid of hemoglobin. They were also extremely fragile and unless care was used in mixing the solid residue and the fluid, even the cell structure was completely destroyed.

SUMMARY

By controlling the freezing and thawing time as well as the concentration of glucose, it was possible to freeze human blood with practically no destruction of the erythrocytes. There seemed to be some leakage of hemoglobin through the cell membrane. This occurred mostly during the first two days following thawing. Pooled specimens of blood that were frozen and thawed deteriorated no more rapidly than the controls after the first forty-eight hours. The same techniques applied to several animal bloods have not been as successful as with human blood. The oxygen-carrying capacity and the ability to type the blood were not altered by freezing. The fragility of the frozen and unfrozen cells was the same. Fragility was decreased in proportion to the per cent of glucose in the blood, however.

Cells frozen at −75° C. were hemolyzed if stored in the ice chamber of an electric refrigerator. We have not found drying from the frozen state successful to date. While it was possible to preserve cell structure, the cells contained practically no hemoglobin.

A STRAIN OF BACTERIUM TYPHOSUM INHIBITED ON BISMUTH SULFITE AGAR*

MARION B. COLEMAN, B.S., ALBANY, N. Y.

THE superiority of bismuth sulfite agar[1, 2, 3] for the isolation of *Bacterium typhosum* and *salmonella* from feces and urine is generally recognized. So much reliance is placed on this medium that the following experience is reported, not to destroy confidence in it, but as an illustration of the importance of using more than one plating medium in any attempt to isolate *Bact. typhosum* from feces.

Cultures of *Bact. typhosum* were isolated from fecal specimens from two patients and a carrier in a limited outbreak of typhoid fever in a rural community in New York state. The microorganism was present in small numbers but was found on bile salts citrate agar media,[4, 5] both before and after enrichment in tetrathionate broth. No typhoid bacilli were isolated from bismuth sulfite agar streaked with the specimens or from that with the enrichment broth. No growth was usually visible with a low power lens (×20) after forty-four hours' incubation of this medium inoculated with pure cultures. When growth occurred, the colonies were generally very small and not typical of typhoid bacilli. Other strains of this species grew characteristically on the same lots of medium.

AN AUTOMOBILE POLLEN TRAP

JAMES A. MANSMANN, M.D., PITTSBURGH, PA.

THIS is a preliminary report to introduce another simple device and new method for pollen slide exposure, namely, an automobile pollen trap. This trap has been in use since April 1, 1941; daily 24-hour exposures have been made and compared with the results of our many gravity counts. Its counterpart is found in the similar types used in airplane exposures by Stakman,[1] Scheppegrell,[2] and Meier and Lindbergh.[3] C. E. Barrett[4] in 1934 reported a few automobile studies which he had made by exposing slides on the rear seat of his car, but he has not made any contributions since that time.

A DESCRIPTION OF THE TRAP

The trap is a small, oblong, somewhat funnel-shaped box with two open ends and an inner slide shelf. It is principally made up of two parts: the outer part, a covering with the widest end or base attached to the windshield; and the inner part, the shelf upon which the slide rests.

We made a cardboard model first, then placed this design on a thin sheet of aluminum to be cut out with a pair of tin cutters. The trap should be made from lightweight material so that it is not easily detached from the car when meeting strong winds. A thin sheet of aluminum about 20 by 8 inches is ideal and sufficient to make a trap.

The length of the shelf should be such as to allow the 3 inches by 1 inch slide to rest easily upon it. The shelf is a keystone-shaped piece of aluminum with the edges on opposite sides folded one-half inch from the ends at right angles to fasten it to the trap at the proper slant. The entire device is fastened together with lightweight rivets, the ends of which can be turned in with a screwdriver. Wind vents are placed at the base to release the air as it rushes through the trap. Four rubber suction cups are used to attach the trap to the windshield.

Since we have been using a convertible car, the windshield is preferred, but with slight modifications the trap could be placed on the roof or elsewhere just as easily. One precaution should be taken on the windshield attachment. Certain state vehicle codes prohibit any obstructive objects on the windshield,

Received for publication, November 9, 1942.

and in these states a permit must be obtained for application thereon. The importance of where the trap is attached was brought out by Stakman in his airplane studies, when he showed that fewer spores were caught in the George trap when attached to the strut above the surface of the lower wing than when held out of the cockpit by hand.

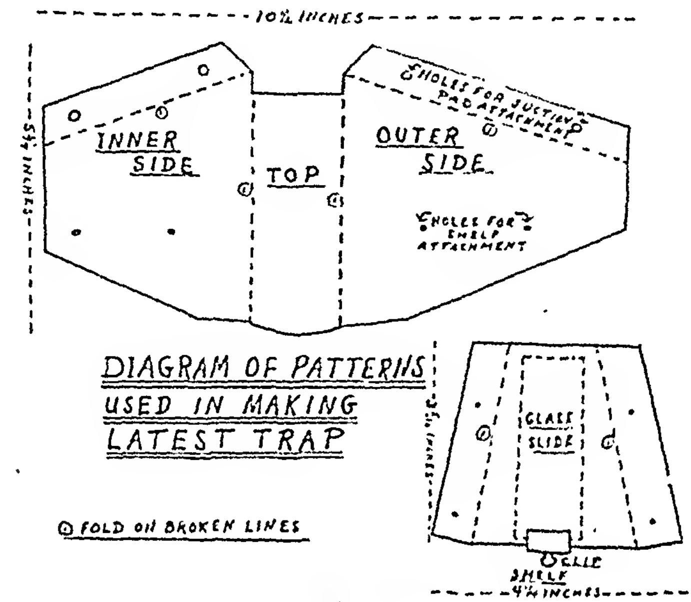

Fig. 1.

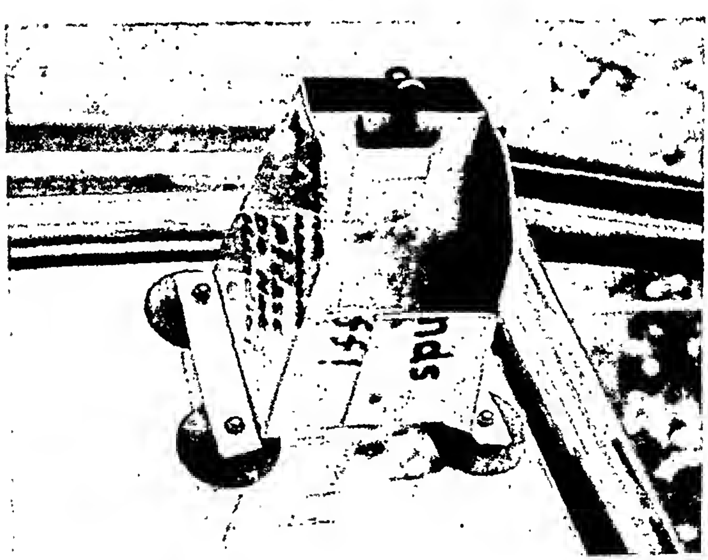

Fig. 2.

The rubber suction cups with a small bolt and nut fastened in the center and a steel clip attached can be purchased at a five-and-ten store. The clips are removed, but can be used to great advantage in anchoring the slide to the shelf. The suction cups allow for easy removal, and the clip makes changing of the slides simple. A one-half inch strip is also turned at right angles at the base on

opposite sides. Two holes are driven through each strip and the suction cups easily bolted on. Wetting the suction surface will give a strong anchorage so that under ordinary driving ranges and meteorologic conditions, the trap will stay in place for about two weeks, after which it should be taken off and re-applied.

Because the windshields vary on different cars, each trap should be fitted to the automobile for which it is to be attached. All the angles are very important, especially the one at which the slide is exposed to the air, and also the one for the protection of the slide from the elements while the car is standing. Of course the design used now favors collection while the car is in motion.

The previous description is a design of a trap which we have used successfully and which we believe with minor changes can be universally adapted to all makes of cars; however, we are constantly experimenting, changing the design and angles to further our knowledge, and hoping for more improvement. We have made many counts with the slide shelf at various angles as it meets the onrushing air, from 30 to 170 degrees. Fig. 3 shows the angle about 75 degrees, but our latest model is placed at 100 degrees. It is our impression that a good deposit of grains is obtained when the slide shelf is placed in a position to meet a great deal of wind resistance.

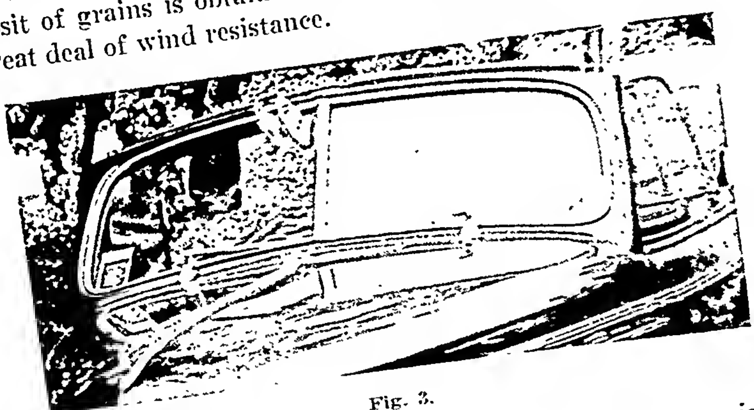

Fig. 3.

Our device has been easy and cheap to construct, a fact we wish to emphasize. It is felt that this trap has the following advantages and with more use can be further developed:

(1) *Simplicity.*—Thus slides for study are easily obtained.

(2) *Mobility.*—The trap can cover any area desired.

(a) This makes pollen studies possible in isolated districts large or small, places in which to look for new types of grains.

(3) *Rapid Sampling.*—This factor will vary with speeds and the exposure angle in the trap. It is from 30 to 150 times faster than the gravity collection.

CHEMICAL

SPECTROPHOTOMETRIC DETERMINATION OF EVANS' BLUE IN SERUM*

O. H. Gaebler, Ph.D., M.D., Detroit, Mich.

The absorption spectra of Evans' blue and oxyhemoglobin are related in such a manner that the dye is readily determined with a spectrophotometer[1] or photoelectric colorimeter[2] in sera showing varying degrees of hemolysis. Constant turbidity introduces no error, but variable turbidity is recognized as a source of uncontrollable errors.[1] In human sera hemolysis is rare if the blood samples are protected with oil, and turbidity is not a common problem. But with dog sera these difficulties are encountered separately or together, particularly in experiments which extend over a period of six hours or more and involve departures from normal conditions.

Results of a preceding study[3] made it possible to choose conditions under which errors due to hemolysis and turbidity can be corrected simultaneously. Correction for turbidity also permits use of 0.8 per cent sodium chloride solution in place of dye-free serum as a blank in spectrophotometric readings. This is advantageous when the dye is given eighteen hours before the experiment, as in "indirect" measurement of changes in plasma volume, and when the dye-free serum is turbid while the dyed sera are clear. In the following procedure one other change in the customary technique is introduced. The sera are diluted with an equal volume of saline solution before reading. This simplifies the calibration and reduces the amount of serum required.

APPARATUS

In the present study a Beckman spectrophotometer[4] equipped with four precision cells of 1 cm. depth was used. Readings in the infrared were required to establish a basis for the simplified technique given below, which is within the range of other instruments.

The cells of the Beckman instrument require 3 c.c. of solution. For admitting to them equal volumes of serum and 0.8 per cent sodium chloride solution the author made a 1.5 c.c. Ostwald-type pipette from capillary tubing having an outside diameter of 7 mm. and a bore of 1.7 mm. The delivery tip of the pipette is 75 mm. long, tapers from 5 mm. to 1 mm. in outer diameter, and has a fine bore. Calibration with water shows that delivery is reproducible to 0.001 c.c.

TECHNIQUE

As in previous methods, paraffin oil is used in the syringes and 15 × 85 mm. specimen tubes to minimize hemolysis. The clotted specimens are centrifuged thoroughly. Attaching a rubber tube to the pipette for suction enables

*From the Department of Laboratories, Henry Ford Hospital.

Received for publication, July 15, 1943.

one to hold the specimens at the level of the eyes, so that serum from small samples can be measured without waste or danger of including cells. While the tip of the pipette passes through the oil, a few bubbles of air should be blown through it. When the pipette has been filled, oil and serum are carefully wiped from the outside and the volume is adjusted.

To 1 volume of each dyed serum one adds 1 volume of 0.8 per cent sodium chloride solution. The extinction (optical density) of the diluted sera is then measured at 750 and 630 mμ. Either dye-free serum diluted in the same manner, or saline solution, may be used as a blank.

CALIBRATIONS

Place 1 volume of the same dye-free serum into each of two cells. To the first cell add 1 volume of saline solution and mix. To the second cell add 1 volume of solution containing 12 mg. of Evans' blue and 8 Gm. of sodium chloride per liter. Using the first cell as a blank, measure the extinction at 750 and 630 mμ. To obtain the coefficients used in calculating Evans' blue concentrations in mg. per liter of undiluted serum, divide the extinction readings by 12. The dilution is ignored, for dyed sera are diluted with saline to the same extent that the saline dye solution is diluted with serum.

As a stock solution of the dye, the one recommended by Gibson and Evans is used. With freshly distilled water and 0.3 Gm. of the dye one prepares 100 c.c. of solution. This is filtered through a sintered glass filter tube, sealed up in ampoules, and autoclaved. The same solution is used for intravenous injection and for preparing the calibrating solution.

The oxyhemoglobin calibration is carried out in the same way, by substituting a saline solution of oxyhemoglobin for the dye solution. The exact concentration of oxyhemoglobin is immaterial, for only the ratio between optical densities at 750 and 630 mμ is needed. The oxyhemoglobin solution mentioned in Table I was prepared by diluting 2 c.c. of citrated blood of a normal dog to 100 c.c. with distilled water, adding 0.8 Gm. of sodium chloride after laking, then filtering through Whatman No. 42 paper.

The turbidity correction is best determined with sera of the type to be encountered in the contemplated study. After diluting the sera with equal volumes of saline, which is also used as the blank, one measures the extinction at 750 and 630 mμ and calculates the ratio between the two values. Somewhat more detailed data required in the present study are shown in Table II. The extinction of eight turbid unhemolyzed dog sera was determined as stated at five or more points between 1000 and 600 mμ. The logarithms of the extinctions were plotted against the negative logarithms of the corresponding wave lengths, and the resulting straight lines[3] were extrapolated to 577 mμ, where traces of oxyhemoglobin interfere with direct measurement of turbidity. From these lines the extinction values shown in Table II were taken. The sera are arranged in decreasing order of turbidity as measured at 630 mμ.

PRINCIPLES OF CALCULATION

The following simultaneous equations present the general problem of determining the concentrations x, y, and z of three substances by spectrophotometry.

$$a_1x + b_1y + c_1z = E_1 \qquad (1)$$
$$a_2x + b_2y + c_2z = E_2 \qquad (2)$$
$$a_3x + b_3y + c_3z = E_3 \qquad (3)$$

One measures the extinction, E_1, E_2, and E_3 of a solution of the three substances at three suitably selected points in the spectrum. The coefficients a, b, and c are determined by calibrating with each substance separately at each of the three points selected. In the present instance E_1 is measured at 750 mμ, E_2 at 630 mμ, and E_3 at 577 mμ. Let y equal the concentration of Evans' blue in mg. per liter of undiluted serum, while x and z represent the oxyhemoglobin concentration and turbidity in any desired units. By calibration one finds that the absorption of the dye at 750 mμ is negligible if the instrument excludes stray light and a concentration of 12 mg. of dye per liter is not greatly exceeded. Thus b_1 is for our purposes zero. Furthermore, one of the reasons for choosing the wave length of 750 mμ is that this makes the ratios a_2/a_1 and c_2/c_1 nearly the same. If these ratios were equal and were represented by k, equations 1 and 2 would yield the following solution for y when b_1 is zero.

$$y = \frac{E_2 - kE_1}{b_2} \qquad (4)$$

TABLE I

EXTINCTION OF OXYHEMOGLOBIN IN DOG SERUM

CELL NO.	SERUM C.C.	OXYHEMOGLOBIN SOLUTION C.C.	SODIUM CHLORIDE 0.8% C.C.	EXTINCTION, 1 CM. CELLS				RATIOS OF EXTINCTIONS		
				750	630	577	540	750	630	577
1	1.5	0.0	1.5	blank						
2	1.5	0.5	1.0	.008	.013	.492	.471	.163	.261	10.0
3	1.5	1.0	0.5	.011	.020	.983	.943	.112	.203	10.0
4	1.5	1.5	0.0	.017	.029	1.50	1.43	.113	.193	10.0

TABLE II

EFFECT OF TURBIDITY AT DIFFERENT WAVE LENGTHS

SERUM NO.	EXTINCTION, 1 CM. CELLS			RATIO OF EXTINCTIONS		
	750	630	577	750	630	577
4	.350	.530	.660	1	1.51	1.89
5	.315	.500	.630	1	1.59	2.00
1	.330	.490	.610	1	1.48	1.85
6	.225	.348	.435	1	1.55	1.93
2	.215	.335	.420	1	1.56	1.95
3	.145	.227	.290	1	1.57	2.00
7	.138	.225	.285	1	1.63	2.07
8	.113	.181	.245	1	1.60	2.17
Average ratios				1	1.56	1.98

In the present case the relationship between the coefficients in equation 3 is such that this simplified solution is sufficiently correct. To demonstrate this, we substitute actual calibration values for the coefficients of x, y, and z in equations 1, 2, and 3. For a_1, a_2, and a_3 we substitute the last set of ratios in Table I. For c_1, c_2, and c_3 we substitute the average ratios at the foot of

Table II. For b_1, b_2, and b_3 we enter values found by calibrating with Evans' blue in the manner described, at 750, 630, and 577 mμ.

$$.113\ x + .0000\ y + 1.00\ z = E_1 \qquad (5)$$
$$.193\ x + .0389\ y + 1.56\ z = E_2 \qquad (6)$$
$$10.0\ x + .0280\ y + 1.98\ z = E_3 \qquad (7)$$

Equation 5

$$z = E_1 - .113\ x \qquad (8)$$

Substitute (8) in (6) and (7)

$$.017\ x + .0389\ y = E_2 - 1.56\ E_1 \qquad (9)$$
$$9.776\ x + .0280\ y = E_3 - 1.98\ E_1 \qquad (10)$$

It is then necessary to divide equation 10 by 575 to obtain the same coefficient for x as in equation 9, and as a result the coefficients of other terms in equation 10 become almost negligible. The final solution is:

$$.03885\ y = E_2 - 1.5634\ E_1 - .00174\ E_3 \qquad (11)$$
$$y = \frac{E_2 - 1.5634\ E_1}{.03885} - .045\ E_3 \qquad (12)$$

Equation 12 differs from equation 4 principally in the presence of an additional term. But if E_3, the extinction at 577, were 2.0, corresponding to 1 per cent transmittance, y, which represents mg. per liter of Evans' blue in serum, would only be changed by 0.09, a matter of less than 1 per cent if the value of y is 10 or over. The value of c_2/c_1 in equations 5 and 6 is 1.56 and that of b_2 is 0.0389. In equation 12 these values have only been altered a few parts per thousand. Whether one should use equation 4, or carry out all calibrations at three points and derive equation 12, is purely a question of whether the two procedures yield as nearly identical results when other types of apparatus and different experimental conditions are employed.

SOURCES OF ERROR

The least complicated determinations, namely, the calibrations with Evans' blue, may be considered first. The same amount of the same serum is present in the blank and the sample under observation; hence, differences in hemolysis and turbidity should not exist. Extinction readings at 750 mμ or longer wave lengths show that this cannot always be taken for granted, for differences in the manner of pipetting or mixing may produce differences in turbidity. If the reading at 750 mμ is zero, the term kE_1 drops out of equation 4. The exactness with which the extinction at 630 mμ, E_2, can be measured, and the constancy of the calibration factor b_2, remain as the limiting factors in accuracy. It is known that extinction measurements between 0.300 and 0.700 are very reproducible with a number of instruments. In the present method the readings will be near the midpoint of this range if the undiluted serum or the calibrating solution contain 12 mg. of dye per liter. This concentration is therefore ideal, and concentrations of 6 to 18 mg. per liter are satisfactory.

The constancy of b_2 was studied in some detail. Four sera were obtained in the course of a week from each of four normal dogs receiving the same diet. Three concentrations of the dye were determined in each of the 16 sera. The data in Table III thus correspond to 48 recoveries of added dye, reported in terms of the observed extinction or optical density. Dividing the values in each line by the concentration of dye indicated in the first column would yield

TABLE III

EXTINCTION OF EVANS' BLUE IN VARIOUS SERA AT DIFFERENT CONCENTRATIONS

Mean of 16 determinations with 12 mg./L in 4 animals									.467	.007

E_2. With the largest concentration of dye employed the mean result was nearly the same for each animal as for the entire series, and the standard deviation of the series is only 1.5 per cent of the mean. In these 16 determinations the technique was precisely as described above for calibration with the dye.

With smaller concentrations two procedures were used. The data in the first two lines of Table III were obtained by using the technique as described, with the single change that the calibrating solutions contained 3 and 6 mg. of dye per liter instead of 12 mg., the sodium chloride content being constant. In the second set of determinations, only the solution containing 12 mg. of dye per liter was added to serum. The extinction having been read, 1.5 c.c. of the sample was transferred to the next cell and mixed with 1.5 c.c. of a diluent consisting of equal parts of the same serum and saline. The extinction was read, and dilution by the same method was repeated once more. Repeated diluting and transferring caused a very slight increase in turbidity, detected at 750 $m\mu$, for which corrections of .003 or less were subtracted. In contrast with the first set, results with the lower concentrations of dye were quite constant, as indicated by the standard deviation. In either set the extinction was very nearly halved when the highest concentration was halved. In a study in which one uses a number of animals under similar conditions it is therefore satisfactory as well as convenient to use an average of four or more calibrations with representative sera of the group and with one reproducible calibrating solution. When pure solutions of the dye were examined, the extinction at the same concentration and wave length was about 6 per cent greater than in serum, and the specific extinction was perfectly constant for different concentrations. If an instrument does not give the latter result with pure solutions, calibrations with various concentrations of the dye of course become necessary.

The accuracy of the correction for hemolysis and turbidity remains to be considered. This is a question of the constancy of k in equation 4. Considering hemolysis first, we find the necessary data in Table I. Whether the extinction values at 750 $m\mu$ are multiplied by 1.5 or 2.0, the error in predicting the values at 630 $m\mu$ does not exceed .005. E_1 is so small that variations in k are unimportant, provided that one uses concentrations of the dye that give a relatively large value for E_2.

When one dilutes the filtered oxyhemoglobin solution prepared as directed for calibration, the ratio of extinctions at 574 and 620 mμ, or 540 and 620 mμ, which is reported as 40:1 in the literature,[1, 2] progressively falls. This may be due in part to the difficulty of avoiding turbidity completely. In any event it introduces no error in the present method. An oxyhemoglobin solution which was obviously turbid gave a value of only 15.2 : 1 for the above ratio, but the ratio between extinctions at 750 and 630 mμ was near the average of those in Table I.

A serious and incompletely understood source of error related to hemolysis in sera from actual experiments is that a hemolyzed dyed serum not infrequently gives a high value, quite out of line with those for preceding and following unhemolyzed dyed sera. This is true whether the present or previous methods of correction for hemolysis are used. The maximum absorption of Evans' blue is near that of methemoglobin and sulfhemoglobin, and conversion of even a few per cent of the oxyhemoglobin in hemolyzed serum to these derivatives would introduce a large error. The difficulty is probably not due to technical errors and may not be due to the above derivatives, but possible contact of the specimens with traces of oxidizing agents or hydrogen sulfide must be excluded.

TABLE IV

VALUES OF k FOUND BY MEASURING THE EXTINCTION AT 750 mμ (E_1) AND 630 mμ (E_2) IN SERA VARYING FROM EXTREME TO MINIMAL TURBIDITY

					.008	.020		.016	+.004
Mean error				.0047					.0025

With reference to turbidity, two situations may be considered. If the control serum and the dyed sera are clear or nearly so, the diluted control serum may be used as a blank. The extinction at 750 mμ will then often be negligible, but will serve as an objective check. Most of the sera in the right half of Table IV could have been subjectively classified as excellent, yet they differ considerably.

If marked turbidity is present in several sera, or in the control serum, the author prefers to make all readings with saline solution as the blank. The value of k in equation 4 was therefore studied in detail, and the results are given in Table IV. Thirty-three sera from normal dogs were diluted with equal volumes of saline and the extinctions were measured at 750 and 630 mμ with

saline solution as the blank. Postprandial as well as postabsorptive sera were included. All sera were of course dye-free. The 16 sera in the left half of Table IV and some of the clear ones in the right half came from specimens drawn and delivered under oil and contained very little oxyhemoglobin. The sera are arranged in descending order of turbidity and are divided into classes with upper limits of 0.030, 0.100, and 0.300 for the extinction at 750 mμ, or E_1. The value of k which most nearly predicts E_2 within these classes is shown, and the mean of the errors in prediction, regardless of sign, is also given. By inspection of the table, it will be noted that an error of .009, or approximately twice the mean error for the turbid sera, is only exceeded in 1 out of 33 sera. This error of .009 corresponds to 0.23 mg. of Evans' blue per liter of serum in the present method, or about 2 per cent if the ideal concentration of 12 mg. per liter is employed.

Evans' blue is removed quantitatively from pure solutions by precipitating calcium oxalate therein. The presence of protein largely prevents this, but the use of serum, as recommended in the original studies on this subject, should be continued. Optical cells used repeatedly with dyed sera presently show extinction values as large as 0.020 at 620 mμ, when filled with saline after thorough rinsing, and should therefore be cleaned with chromic acid or a detergent between determinations. The extinction of the dye at 615 to 630 mμ is not notably altered by changes in pH from 3.0 to 8.0, but stronger alkali changes the color. Sodium hydrosulfite destroys the color in alkaline and weakly acid solutions, an intermediate red stage being noted in the latter.

SUMMARY

Technique for spectrophotometric determination of Evans' blue (T-1824) in serum, with a single correction for both turbidity and hemolysis, is described, and sources of error are examined. When the concentration of dye is 12 mg. per liter and no correction for turbidity or hemolysis is needed, the probable error of individual determinations is 1 per cent. When the correction for hemolysis and turbidity is large, a total error of 4 per cent is possible. To exclude it an adequate number of observations must be made under uniform experimental conditions. Badly hemolyzed dyed sera not infrequently yield unreliable results suggesting the presence of methemoglobin. Any technical errors that could result in formation of this compound or sulfhemoglobin must be avoided. Advantages of the dye over those previously used are well-known; its principal disadvantage is the readiness with which it is adsorbed on glass, calcium oxalate, and protein.

DENSITY FINDINGS WITH HEPARIN IN BLOOD, PLASMA, AND SERUM*

Alfred L. Copley, M.D.,† and Mary E. Whitney, Kansas City, Kan.

WHILE studying viscosities of heparinized blood we[1] found a decrease in the density with heparin. This led us to investigate further the influence of heparin added in various units to blood, plasma, and serum.

The densities were determined by pyknometry, and calculated by the equation, $\text{Density} = \frac{\text{Weight}}{\text{Volume}}$. Two Nicol tube pyknometers with capacities of 1.2517 c.c. and 2.2869 c.c. were used. The blood was obtained in clean dry 50 c.c. syringes. Adequate accuracy to measure 0.3 c.c. quantities of liquid in question was provided by the use of precision Pyrex pipettes, Mohr Measuring Type, with capacities of 0.1 and 0.2 c.c. It was found essential that the glassware employed be rigorously cleaned.

Blood was taken from three human beings and diluted 9:1 with anticoagulant solutions. Not less than 9 c.c. of blood were used for each dilution. Two, 5, 25, and 125 units of heparin (110 Murray-Best units per milligram of the sodium salt) were contained per c.c. of these blood systems. For controls, 0.2 per cent sodium oxalate, 0.2 per cent potassium oxalate, and 0.3 per cent sodium citrate in equal volumes of blood dilution were used. One portion of each of the blood systems was centrifuged at 3,000 revolutions per minute for twenty minutes, and the supernatant plasma was tested for density. All tests were run continuously within six hours following blood withdrawal. With increasing amounts of heparin, the density decreases in both blood and plasma, but not in linear proportion. Samples containing heparin show lower density than the controls. Results are compiled in Table I. Similar results, as with sodium oxalate, were obtained with potassium oxalate and sodium citrate.

Serum from two human beings, three dogs, and one sheep was obtained six hours following blood withdrawal by centrifugation at 3,000 revolutions per minute for twenty minutes. Three-tenths c.c. solutions of 10, 50, 250, and 1,250 units of heparin in distilled water and, as control, 0.3 c.c. distilled water were added to 3 c.c. serum, and pyknometry was done within three hours. In all instances the density was lowered with heparin. The decreases were more marked with higher heparin concentration, although they were never directly proportional (Table II).

Since Chargaff and Olson[2] found that protamine deionizes and flocculates heparin, we have determined the influence of various amounts of heparin on the density of a 1.5 per cent protamine sulfate‡ solution in physiologic saline. Following centrifugation of the protamine solution at 1,500 revolutions per

Received for publication, April 12, 1943.

minute for ten minutes, heparin solutions were added to the decanted fluid. In each case the density was decreased by heparin.

Sheep	29	1.0233		1.0224	1.0223	

SUMMARY

Heparin has a specific lowering action upon the density of the four systems of blood, plasma, serum, and protamine sulfate solution. Increasing amounts of heparin decrease the density more markedly, but not in linear proportion. Data are not, as yet, sufficiently extensive to draw any conclusions as to the mechanism of this action.

VI. A SIMPLE AND ACCURATE METHOD FOR QUANTITATIVE DETERMINATION OF BILE ACIDS AND SALTS IN BILE

Lester M. Morrison, M.D., Philadelphia, Pa.

In 1940, in this journal, the author, in collaboration with W. A. Swalm, gave a brief, preliminary description of a simple, stalagmometric method for the quantitative determination of bile salts in urine and bile.[1] During the intervening years, this procedure has been utilized in the author's laboratory as one of the routine laboratory aids for the estimation of hepatic function in diseases involving the liver or biliary tract.[2,3] This experience in application of the procedure in the analysis of samples of bile obtained by intubation of the duodenum has indicated some possible sources of error and the need of amplifying the original description of the technique.

APPARATUS

Fig. 1 illustrates the stalagmometer, which may be obtained from the Precision Thermometer and Instrument Co., of Philadelphia, Pa. It consists of a pipette to which is attached a capillary tube of 7.5 cm. in length and 0.106 cm. in diameter. Graduations A and B on the pipette define a volume of 13.2 c.c. Changes in surface tension are measured in terms of numbers of drops falling from the capillary outlet as the fluid contained in the pipette flows from graduations B to A.

In order to prevent plugging of the capillary tip with precipitated particles, the stalagmometer should be cleaned each day at the beginning and at the end of a series of analyses by drawing cleaning solution as high as the safety bulb above graduation B. After draining off the cleaning solution, first water is drawn into the apparatus in a similar manner and then an alcohol-ether mixture. If, in this process of cleaning, water enters the needle valve, this should be dried first by an alcohol-ether mixture and then by a current of air. Finally, the stalagmometer is dried by a current of air.

CALIBRATION OF THE STALAGMOMETER

For a given volume of water or bile, different stalagmometers may deliver varying numbers of drops. Hence, each stalagmometer should be calibrated in order to determine corrections to be applied in calculation of results. For this purpose, a stock solution is prepared containing 100 mg. of pure cholic acid in 100 c.c. of 0.01 NaOH. From this stock solution, serial dilutions are made up by adding each of the following aliquots, viz., 1.0, 2.0, 3.0, 4.0, 6.0, and 8.0 c.c. water in 100 c.c. volumetric flasks. These solutions are diluted to approximately 98 c.c. To each of these solutions, 6 N hydrochloric acid is added drop by drop with agitation until one drop, transferred by means of a stirring rod to a strip of filter paper saturated with tropeolin 00, shows a change from yellow to pink. After acidification, all solutions are diluted to 100 c.c.

Calibration of the stalagmometer should include first determinations of numbers of drops of distilled water falling from the stalagmometer during the

Received for publication, April 16, 1943.

flow of the water from the upper to the lower graduation. By means of the needle valve, the rate of fall of the drops must be adjusted to 30 per minute. Then readings are made of each of the diluted and acidified solutions of cholic acid prepared as described above.

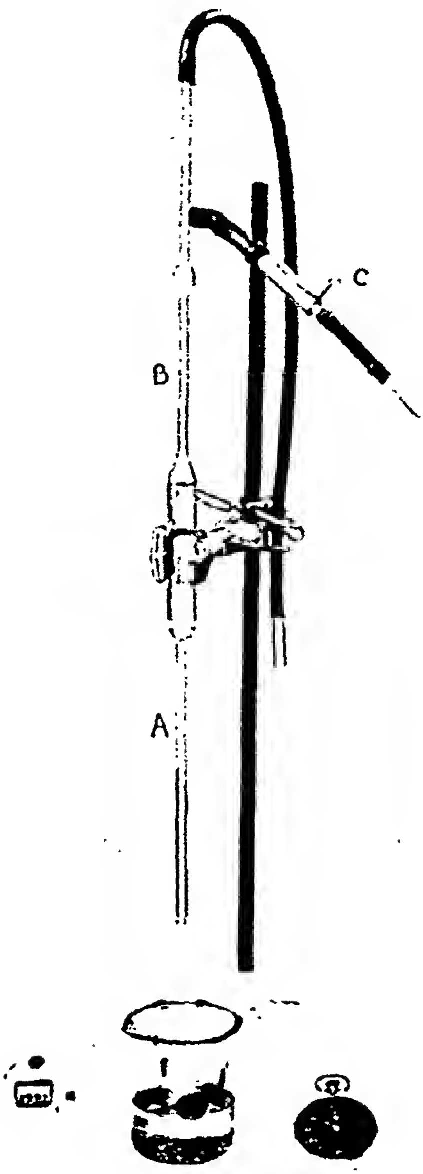

Fig. 1.

Concentrations of cholic acid in water corresponding to varying numbers of drops from one stalagmometer are shown in Table I. A similar table may be prepared for the particular stalagmometer being calibrated, or the readings may be corrected to conform with those in Table I. The procedure for determining corrections for a particular stalagmometer, A, is illustrated by the following example.

Before numbers of drops from stalagmometer A are referred to Table I for calculations of results, the numbers of drops must be multiplied by 0.94.

ANALYSES OF SPECIMENS OF BILE OR BILE FRACTIONS

Chart I shows the relationship between decrease in surface tension of water, as determined by the stalagmometer, and the concentration of cholic acid in solution. The maximum rate of rise of the curve lies within the range of concentrations from 2.0 to 5.2 mg. of cholic acid per 100 c.c. corresponding to stalagmometric readings from 157 to 190 drops. Within these levels, changes in concentration of cholic acid have greater effects upon the numbers of drops falling from the stalagmometer than do similar changes in other parts of the curve. In other words, this range represents the sensitive part of the curve. All readings should be maintained within the limits of 157 to 190 drops, as reported in Table I.

CHART I

CONCENTRATION OF CHOLIC ACID IN WATER MG. PER 100 C.C.	NUMBER OF DROPS FROM A	NUMBER OF DROPS TABLE I	RATIO DROPS—TABLE I / DROPS—FROM A
0	156	144	0.92
2.0	166	157	0.94
4.0	192	183	0.95
6.0	204	192	0.94
	Average	=	0.94

An inspection of the bile fraction will suggest the proper range of dilution. Fluid specimens are diluted 10 or 25 times and viscid samples 50 to 100 or even 200 times.

A measured amount of bile (0.5 to 2.5 c.c.) is diluted with water to about 24 or 49 c.c. in a 25 or 50 c.c. glass stoppered volumetric cylinder. It is acidified with 6 N hydrochloric acid to the end point of the tropeolin 00 test paper using an outside drop test, and it is made up to the 25 or 50 c.c. volume mark.

TABLE I

TABLE FOR CALCULATION OF CONCENTRATIONS OF CHOLIC ACID FROM STALAGMOMETRIC READINGS

NUMBER OF DROPS	0	1	2	3	4	5	6	7	8	9
140					0	0.50	0.80	1.00	1.20	1.30
150	1.40	1.50	1.60	1.70	1.80	1.90	1.95	2.00	2.05	2.10
160	2.15	2.20	2.25	2.30	2.35	2.40	2.45	2.50	2.55	2.60
170	2.70	2.80	2.90	3.00	3.10	3.20	3.30	3.40	3.50	3.60
180	3.70	3.80	3.90	4.00	4.10	4.30	4.40	4.60	4.80	5.00
190	5.20	5.50	5.80	6.20	6.60	6.90	7.30	7.60	8.00	8.30

Values in the table give mg. per 100 c.c. of cholic acid.

The stalagmometer is filled by aspiration and allowed to drip into a 10 or 25 c.c. cylinder. The flow of drops is adjusted to 30 drops per minute or less. The drops are counted in the usual manner, but a reading is taken when the solution in the cylinder reaches a level of an even c.c. mark. Another reading is taken when the solution reaches the next c.c. level. The difference in readings represents the number of drops in 1 c.c. of solution. A reading can be taken on the next c.c. as a check. A previous calculation from the desired range

of readings (160 to 190 drops) and the volume of the stalagmometer (13.2 c.c.) will indicate when the number of drops per c.c. of the solution will give a total reading within the desired range.

$$\frac{160}{13.2} \text{ to } \frac{190}{13.2} \text{ is 12 to 14.4 drops per c.c.}$$

If the number of drops per c.c. is below the desired range, a fresh solution of higher concentration is prepared.

If the number of drops per c.c. is above the desired range, the solution is diluted 1:1 with adjustment of the pH to the specified end point. If the reading indicated more than a 1:1 dilution, it is advisable to prepare a fresh solution.

The stalagmometer is rinsed and filled with the new solution and the counting begun. If the preliminary test shows the reading is within the desired range, the stalagmometer reading of the full volume is taken.

As the solution in the stalagmometer flows out, the rate of flow diminishes to 20 drops a minute. It can be readjusted to 30 drops by a manipulation of the needle valve without affecting the reading.

CALCULATION OF RESULTS

Stalagmometric readings for 2 or more dilutions of the bile, giving numbers of drops within a range of 160 to 190, are referred to a table prepared for that particular instrument; or readings corrected for the instrument, as described above, are referred to Table I. The concentration of cholic acid listed in the table corresponding to the reading is then multiplied by the dilution of the bile.

For example, a sample of bile diluted 1:100 gives, in duplicate determinations, 185 and 187 drops. The mean of 186 drops in Table I indicates a concentration of 4.4 mg. per 100 c.c. Hence, the concentration of bile salts as cholic acid in the bile fraction is 4.4 × 100 = 440 mg. per 100 c.c.

TABLE II

SUMMARY OF RECOVERIES OF CHOLIC ACID ADDED AS DESOXYCHOLIC ACID, CHOLIC ACID, OR BILE SALTS TO FRACTIONS OF BILE DRAINED FROM HUMAN SUBJECTS

SOURCE OF CHOLIC ACID ADDED TO BILE	RANGE OF CONCENTRATION OF CHOLIC ACID IN BILE MG. PER 100 C.C.	CHOLIC ACID ADDED MG. PER 100 C.C.	NO. OF EXPERIMENTS	AVERAGE RECOVERY PER CENT OF ADDED CHOLIC ACID	AVERAGE DEVIATION
Cholic Acid	103 – 138	25 – 140	7	104	±5
	360 – 480	75 – 500	6	99	±9
	615 – 990	240 – 960	9	108	±4
Desoxycholic Acid	300 – 390	38 – 380	12	96	±11
	570 – 700	60 – 600	7	97	±6
Bile Salts	103 – 107	47 – 100	3	104	±3
	300 – 480	42 – 500	13	98	±5
	615 – 990	32 – 960	18	100	±4
	Averages		75	103	±7.3

PROBABLE ERROR OF THE METHOD

The accuracy of the method has been determined by a series of 75 recovery experiments summarized in Table II. The cholic acid concentrations of samples

of bile drained from human subjects were reinforced by the addition of either pure cholic acid, pure desoxycholic acid, or a commercial (Fairchild's) preparation of bile salts. Analyses of several samples of this commercial preparation of bile salts yielded an average of 34 per cent of cholic acid.

Quantities of cholic acid added to the bile samples gave theoretical increases varying from approximately 10 to 100 per cent above the original levels determined in these samples. Average recoveries of added cholic acid for the different levels of cholic acid concentration in the samples of bile varied from 96 to 108 per cent. For the 75 analyses, the average recovery was 103 per cent with an average deviation of ± 7 per cent.

SUMMARY

This report summarizes experiences over a period of three years with a simple, stalagometric method for determination of bile acid and salts in samples of bile drained by intubation of the duodenum.

In the description of the technique, particular emphasis has been placed upon conditions of dilution and acidification of samples of bile, and the range of stalagmometric readings which have yielded most satisfactory results.

A series of 75 experiments have given an average recovery of 103 ± 7.3 per cent of cholic acid, added either as cholic acid, desoxycholic acid, or a mixture of bile salts to samples of bile drained from human subjects.

THE SEPARATE DETERMINATION OF THE FATTY ACID FRACTION AND OF THE NEUTRAL FAT PLUS STEROL FRACTION IN FECES*

J. C. Forbes, Ph.D., and T. T. Atkinson, Jr., B.S., Richmond, Va.

The separate determination of fatty acids and of the neutral fat portion in feces theoretically offers valuable information as to the efficiency of fat digestion and absorption. Analytical procedures have been described by a number of investigators, e.g., Tidwell and Holt,[1] Fowweather,[2] Holt, Courtney, and Fales,[3] and Saxon,[4] but all the procedures are quite long and require considerable manipulation. Several years ago a relatively simple method for the determination of neutral fat and cholesterol in animal tissue was described by Outhouse and Forbes.[5] Since a simple method for the determination of fat and free fatty acids should be of considerable value in clinical chemical lab-

*From the Department of Biochemistry, Medical College of Virginia.
Received for publication, May 3, 1943.

oratories, it was decided to determine whether this method could be modified in order to allow the independent determination of the neutral fat fraction and fatty acids in a mixture of the two. After attempting various procedures, a method was finally worked out and applied with satisfactory results to fecal analyses. No distinction is made between fatty acids present as soaps or as free fatty acids. Sterols are included in the neutral fat fraction. Bloor's oxidative technique[6] with minor modifications was used throughout.

Determination of Neutral Fat Plus Sterols.—Approximately 3 Gm. of feces are air-dried, as recommended by Tidwell and Holt,[1] ground thoroughly, and last traces of moisture removed in a desiccator. About 0.3 Gm., accurately weighed, is ground in a mortar with 5 Gm. of doucil,* an artificial zeolite, and transferred quantitatively to a 125 c.c. glass-stoppered Pyrex bottle. 100 c.c. of chloroform are added, followed by 0.8 c.c. of 10 per cent sodium hydroxide to precipitate the free fatty acids as their sodium soaps. The bottle is shaken well and set aside with occasional shaking for several hours and preferably left overnight. The chloroform solution is filtered through a fat-free rapid filter paper, and 2 to 5 c.c., depending upon the apparent amount of fat present in the sample, are transferred to a 125 c.c. glass-stoppered Pyrex Erlenmeyer flask. The flask is placed in warm water, and the solvent is completely removed with the aid of a stream of air played upon the surface of the liquid. Five c.c. of a silver chromate solution in sulfuric acid are added, and this is followed by 3 c.c. of 1 N potassium dichromate. The flask is stoppered loosely, the solution gently mixed, and the flask put in an electric oven at 95° C. The flasks are removed after about five minutes, rotated to stir up the contents, stoppered tightly, and replaced in the oven for two hours. Control flasks using the same amount of silver chromate and potassium dichromate solutions are run at the same time. The stoppers are removed immediately after the flasks are taken from the oven, and shortly thereafter approximately 60 c.c. of cold distilled water are added. Ten c.c. of 10 per cent potassium iodide are added without stirring, and the liberated iodine is titrated without delay with 0.1 N sodium thiosulfate, using 1 per cent starch solution as indicator. A small granule of sodium hydroxide should be added to the potassium iodide solution to prevent decomposition. The starch solution should not be added until the yellow color of the iodine has practically disappeared. The difference between the titration value of the control and unknown solution is a measure of the lipids present in the unknown sample taken for analysis. A value of 3.6 c.c. of 0.1 N sodium thiosulfate is taken as equivalent to 1 mg. of neutral fat. Sterols are extracted along with the neutral fat and appear in the calculations as neutral fat. Phospholipids do not interfere as they are removed by the doucil.

SPECIAL REAGENTS REQUIRED

Silver Chromate Reagent.—To 5 Gm. of silver nitrate dissolved in 25 c.c. of water are added 5 Gm. of potassium dichromate dissolved in 50 c.c. of water. The precipitated silver dichromate is separated by centrifugation, washed twice with water by centrifugation, and then dissolved without drying in 500 c.c. of pure concentrated sulfuric acid.

*The doucil was obtained from W. A. Taylor and Company, Baltimore, Maryland.

Sodium Thiosulfate Standard (0.1 N) Solution.—Weigh out 25 Gm. of ordinary C.P. sodium thiosulfate or 24.83 Gm. of the pure dry recrystallized salt. Dissolve in water and dilute to a liter. Boiled distilled water must be used. This solution is standardized against acid potassium iodate. Weigh accurately 0.3249 Gm. of acid potassium iodate. Dissolve in 50 c.c. of water, heating gently if necessary. Transfer the solution to a 100 c.c. flask, rinsing the beaker carefully, and dilute to volume with water. This solution is exactly decinormal. Pipette 25 c.c. into an Erlenmeyer flask, add 1 gram of potassium iodide dissolved in a little water and a few cubic centimeters of dilute hydrochloric acid. Titrate immediately with the thiosulfate solution, using starch as indicator.

Determination of Soaps Plus Free Fatty Acids.—A weighed amount, 0.1 to 0.2 Gm., of the thoroughly ground sample is transferred to a 125 c.c. Pyrex glass-stoppered bottle and 4 c.c. of 1:4 sulfuric acid added (1 vol. of sulfuric acid plus 3 vols. of water). The bottle is warmed gently on a hot plate so as to convert all soaps to free fatty acids. This heating should be continued until the solution is close to the boiling point and considerable water has condensed on the sides. The flask is allowed to cool and 5 Gm. of doncil added. After mixing, 100 c.c. of chloroform are added, and the bottle is shaken thoroughly, then is set aside with occasional shaking for several hours, and preferably is left overnight. The chloroform solution is filtered through a fat-free rapid filter paper, 2 to 5 c.c. of the filtrate are evaporated to dryness in an oxidation flask, and the total lipid content is determined by the oxidation method already described. Since the oxidation value of the fatty acids approximates that of the corresponding fat, 3.6 c.c. of 0.1 N sodium thiosulfate has been taken as equivalent to 1 mg. of lipid material, whether present as neutral fat or fatty acids. The difference between the lipid content per 100 Gm. as determined above and that obtained for the neutral fat portion gives the fatty acids present as soaps or as free fatty acids.

TABLE I

RECOVERY OF NEUTRAL FAT AND FREE FATTY ACIDS FROM MIXED SOLUTIONS

EXPERIMENT NUMBER	LIPIDS PRESENT			LIPIDS RECOVERED				
	TOTAL GM.	NEUTRAL FAT GM.	FATTY ACID GM.	TOTAL GM.	NEUTRAL FAT OBTAINED GM.	NEUTRAL FAT CORRECTED GM.	FATTY ACID OBTAINED GM.	FATTY ACID CORRECTED GM.

2	.1451	.0445	.1006	.1363	.0470	.0450	.0893	.0913
3	.0955	.0417	.0538	.0952	.0409	.0389	.0543	.0563
4	.1086	.0502	.0584	.1068	.0520	.0500	.0548	.0568
5	.1086	.0502	.0584	.1075	.0544	.0524	.0531	.0551
6	.1829	.1056	.0773	.1812	.1130	.1110	.0682	.0702
7	.1531	.0773	.0758	.1481	.0812	.0792	.0669	.0689
8	.1147	.0630	.0517	.1140	.0622	.0642	.0518	.0538
9	.2109	.0902	.1207	.2092	.0992	.0972	.1100	.1128
Total	1.2585	.5804	.6781	1.2341	.6113	.5973	.6228	.6408
			Per cent error	−1.1	+5.3	+2.9	−8.1	−5.5

Before applying the method to fecal analyses, it was necessary to determine the recovery from known solutions of fat and fatty acid. In these experiments a weighed amount of recrystallized tripalmitin and stearic acid was dissolved in 200 c.c. of chloroform. Approximately half of the solution was transferred to a 125 c.c. glass-stoppered bottle containing 5 Gm. of doncil, after which

0.8 c.c. of 10 per cent sodium hydroxide was added and the solution thoroughly shaken. The remainder was transferred to a similar bottle containing 5 Gm. of doneil plus 4 c.c. of 1:4 sulfuric acid. Both bottles were thoroughly shaken and allowed to stand with occasional shaking for several hours, and usually left overnight. They were then filtered and analyzed as previously described, and the amount present in the original 200 c.c. of solution was calculated. In the calculations 3.60 c.c. of 0.1 N sodium thiosulfate have been taken as equivalent to 1 mg. of tripalmitin and 3.66 c.c. for 1 mg. of stearic acid. The experimental results are shown in Table I. The values for neutral fat are on the average approximately 5 per cent too high. This is due primarily to a slight solution of the fatty acids in the chloroform, even in the alkaline medium. Experiments with pure stearic acid under the condition used showed an average solubility of approximately 1 mg. per 100 c.c. of chloroform. If corrections are made for this solubility, the per cent recovery is quite satisfactory. In the usual fecal analysis an error of this magnitude can be neglected. This has been done in obtaining the experimental results recorded in Table II.

TABLE II

LIPID ANALYSIS OF NORMAL FECES

EXPERIMENT NUMBER	NEUTRAL FAT PLUS STEROLS	FATTY ACIDS PLUS SOAPS
	Per cent	Per cent
1	8.3	10.9
2	6.5	8.2
3	10.9	2.9
4	7.5	9.3
5	6.7	10.9
6	8.7	7.1
7	8.0	8.9

All values are given in per cent dry weight.

Experiments with calcium stearate following the procedure described for soaps and free fatty acids gave satisfactory recovery of the stearic acid. The analytical results obtained on normal feces and recorded in Table II are in good agreement with the commonly accepted normal values. Although approximately 0.3 Gm. is very suitable for normal feces, the sample should be reduced to about half this value if the fat content is apparently high.

SUMMARY

A relatively simple method for the determination in feces of neutral fat plus sterols, free fatty acids, and soaps is described.

A SIMPLE AND ACCURATE METHOD FOR THE DETERMINATION OF MERCURY IN BIOLOGIC MATERIAL*

THOMAS H. MAREN, A.B., NEW BRUNSWICK, N. J.

THE use of dithizone as a colorimetric reagent for mercury is due to Fischer and Leopoldi,[1] and Fischer,[2] and has recently been adapted to use in biologic materials by Laug and Nelson.[3]

The colorimetric method is accurate enough to supplant tedious older methods, which depend upon electrolysis or amalgamation of the metallic element for its ultimate determination, or upon titration methods involving iodide or thiocyanate. The present method has the advantage of extreme simplicity, speed, and a broad range. A single analysis should not take longer than five minutes, after digestion of organic material is completed.

DISCUSSION

The investigators cited above have regarded copper as an interfering element. They separated copper from mercury at pH 1 by the use of KI, KBr, or $Na_2S_2O_3$. Finally, the mercury dithizonate is formed at pH 6. Both of these steps are eliminated in the present method. The number of operations in the procedure are thereby considerably reduced. Formation of the mercury dithizonate at pH 1 further eliminates the problem of maintaining lead free reagents and apparatus. At pH 6 dithizone is extremely sensitive to lead, and in the earlier methods special consideration of this was required.

We have found that copper need not interfere, if the proper conditions of pH are maintained. In acid solution, dithizone reacts with gold, palladium, platinum, mercury, silver, copper, and bismuth. The latter do not, however, react at pH 0 to 1.0. In 50 c.c. 0.25 N HCl, 1,000 mg. of copper does not change the color of dithizone reagent. Silver does not react in the presence of excess halogens. Mercury and the noble metals alone, therefore, react with dithizone under these conditions, and the latter will rarely interfere with analysis of biologic materials. The yellow color of the dithizone-mercury complex may then be regarded as specific in the presence of 0.25 N HCl and in the absence of the noble metals. The presence of 5 to 7 c.c. sulfuric acid (from the organic digestion) brings the pH to 0.2 and does not alter the above considerations in any way.

Fig. 1 shows that at 490 $m\mu$ conditions are proper for a "mixed color" determination of mercury with a spectrophotometer. Here the green dithizone solution transmits rather freely, and the yellow mercury complex has its absorption maximum. Solutions to be measured will range from green through light green and dark yellow to light yellow. The standard or unknown is measured against the dithizone solution. Beer's law is obeyed; the optical density has a linear relation to the concentration of mercury.

In the digestion of organs and urine, it was not found necessary to connect a water-cooled condenser to the digestion flask. A mixture of equal weights of sulfuric and nitric acids was used. It was found that the digestion proceeds

*From the Wallace Laboratories, Inc.

Received for publication, May 28, 1943.

smoothly if about three times as much mixed acid as organic material is used. Occasional charring may occur; the addition of small supplementary amounts of nitric acid will obviate this. The digestion is carried out in a micro-Kjeldahl flask with ground glass joint. The digestion may proceed with an air-cooled condenser rather than under reflux. We have found that elimination of the water-cooled condenser considerably decreases the time of digestion and no loss of mercury is involved. Table I shows recovery of mercury using the method described below. Table II shows noninterference of copper over a wide range.

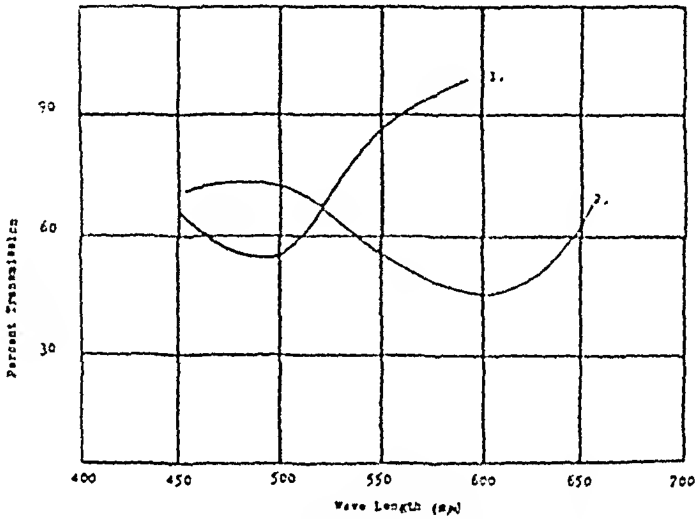

Fig. 1.—1. Mercury-dithizone complex ($CHCl_3$ solution). 2. Dithizone (in $CHCl_3$). (Readings from Coleman spectrophotometer. Solutions shaken with .25 N HCl in all cases.)

REAGENTS

1. Sulfuric Acid. Analytical Reagent.

2. Nitric Acid. Analytical Reagent. An equal weight mixture of 1 and 2 was used as the stock digestion solution.

3. Hydroxylamine hydrochloride chemically pure. A 20 per cent aqueous solution is used to destroy any excess nitric acid.

4. 0.25 N HCl. From chemically pure HCl.

5. Dithizone solution. 10 mg. dithizone (Eastman) dissolved in 1 liter of chloroform. This is a light green solution. (Transmission curve shown in line 2 of Fig. 1.) 10 c.c. will be entirely converted to the metal salt by 25 micrograms of mercury. The resulting yellow solution is plotted in line 1 of Fig. 1.

PROCEDURE

To about 5 Gm. of organic material add 10 to 15 c.c. of acid digestion mixture in a long-necked Kjeldahl flask, to which is fitted (using a glass joint) an air condenser about 18 to 20 inches long. Digestion begins spontaneously. After ten minutes apply a gentle flame, and increase the heat gradually until the full flame of the burner is used. After an hour the nitric acid fumes disappear and the digestion is finished.

The ash solution is cooled and poured into a separatory funnel containing 25 c.c. of .25 N HCl and 2 c.c. of 20 per cent hydroxylamine hydrochloride. Add 10 c.c. of dithizone reagent solution, shake 50 times, and collect the $CHCl_3$

TABLE I

layer. The mercury dithizone thus formed is very sensitive to light and should not be exposed to bright sunlight. The extract is measured with the spectrophotometer against dithizone at 490 mμ, and the reading is compared with that on a standard curve.

This calibration curve, conforming to Beer's law, sets optical density against concentration of mercury. The standards may be prepared by adding known amounts of mercury (not exceeding 25 mg.) to 25 c.c. of 0.25 N HCl, and extracting, as above, with 10 c.c. dithizone. The optical density of the extract is measured against that of dithizone solution at 490 mμ. We have not found it necessary to include the other reagents used in the digestion in this standardization. They have no effect on the final color. Twenty-five milligrams of mercury will convert all the dithizone to the yellow mercury complex. Larger amounts therefore must be determined by taking aliquot samples of the unknown after digestion.

An alternate procedure, which is accurate enough for general biologic work, may be employed in the absence of a spectrophotometer. In this method the mercury is titrated with dithizone solution. For the concentration of dithizone used, 1 c.c. of the solution is equivalent to 2.5 mg. of mercury. Small portions of dithizone are added to the funnel, which contains, as above, the mercury sample 0.25 N HCl and hydroxylamine hydrochloride. The end point is reached when the dithizone in the funnel is olive green, indicating slight excess of unreacted reagent. The number of micrograms of mercury in the sample is equal to the cubic centimeters of dithizone solution x 2.5. It is advisable, however, to standardize the dithizone solution by actual titration against a known amount of mercury.

The titration method is also useful when over 25 mg. of mercury are present. In this case the spectrophotometer cannot be used, for 10 c.c. of dithizone reagent is completely converted to the mercury salt, and a "mixed color" determination is impossible. Successive additions of dithizone, however, will yield the green and point color. The total amount of dithizone added will then be a measure of the mercury present.

SUMMARY

A rapid, sensitive, colorimetric method for analysis of mercury, particularly in biologic materials, has been presented. Dithizone in $CHCl_3$ reacts with mercury at pH 1 (only gold palladium and platinum would interfere) to form a yellow complex which may be analyzed by the "*mixed color method*" in the spectrophotometer, or may be used as the basis for direct titration of the mercury.

The author wishes to thank Miss Blanche Kohut for her technical assistance.

DETERMINATION OF DIODRAST-IODINE IN URINE AND IN FILTRATES OF PLASMA*

A. C. CORCORAN, M.D., AND IRVINE H. PAGE, M.D.
INDIANAPOLIS, IND.

THE accurate determination of diodrast-iodine has become widely practiced in the determination of diodrast clearance and of functioning tubular secretory mass (Smith, Goldring, and Chasis,[1]). The following simple procedure has proved very satisfactory in daily use during the past two years. The method was orginally developed from Alpert's procedure[2] as a titrimetric procedure in which diodrast-iodine was determined as iodate by thiosulfate titration. The colorimetric procedure used by Flox, Pitesky, and Alving[3] was then applied to it without modifying other aspects of our method.†

Principle.—"Duponol PC"‡ is used to stabilize recovery of diodrast from plasma filtrates. Diodrast-iodine is oxidized by treatment with bromine water in acid solution. The excess of bromine is removed by addition of sodium formate, and the iodate iodine (Flox, Pitesky, and Alving,[3] 1942) content is determined photocolorimetrically.

Preparation of Reagents.—1. Acid $ZnSO_4$ with Duponol PC. 27 Gm. $ZnSO_4$ and 30 c.c. of approximately 1 N H_2SO_4 are made up to about 1 liter with water. One gram of Duponol PC is added and put in solution with the least possible shaking. Ten c.c. of the mixture in about threefold dilution are titrated with 0.15 N NaOH, using phenolphthalein as indicator. The pink color of the end point should persist for one minute. From the value obtained in the titration, the acid $ZnSO_4$ solution is diluted until 10 c.c. of it exactly neutralizes 11.2 c.c. of 0.15 N. NaOH.

2. 0.15 N NaOH. The solution is prepared by dilution of "carbonate-free" NaOH in recently boiled distilled water. It is protected from atmospheric CO_2 by a soda-lime trap. Plasma filtrates prepared as directed below should be of pH 6.7 to 6.8. The recovery of diodrast from plasma becomes less complete as

*From the Lilly Laboratory for Clinical Research, Indianapolis City Hospital.
†Details of this procedure were furnished us before its publication through the kindness of Dr. Alving.
‡E. I. Du Pont and Company, Wilmington, Del.
Received for publication, May 31, 1943.

the pH range 6.0 to 6.2 is reached, while the plasma "blank" increases rapidly about pH 6.8. The accuracy of preparation of reagents should therefore be checked by the determination of pH in plasma filtrate before the solutions are placed in use. The addition of Duponol PC increased the pH range over which recovery of diodrast-iodine from plasma is possible and permits full recovery at plasma dilutions of less than 1:15.

3. Bromine water. An excess of liquid bromine is added to 500 c.c. of distilled water. The mixture is stored in the refrigerator, water and bromine being replenished as required.

4. Sodium formate. 10 Gm. of reagent grade sodium formate are dissolved in 100 c.c. of water. The solution is kept in the refrigerator and made freshly each week.

5. Alkaline KI. 50 Gm. of KI, reagent grade, are dissolved in approximately 100 c.c. of 0.01 N NaOH. The solution is protected from light by storage in an amber dropping bottle.

PROCEDURE

1. Precipitation of plasma proteins: A modification of the Somogyi zinc precipitation is used. To one volume of heparinized plasma are added five volumes of acid $ZnSO_4$ with Duponol. The mixture is allowed to stand for about thirty minutes. Five volumes of 0.15 N NaOH are then added dropwise with constant agitation. The mixture is filtered at once through a No. 1 Whatman paper *without* prior centrifugation.

Because of the high dilutions (1:1000) used, comparable precipitation of protein from urine samples is unnecessary except in the presence of gross proteinuria or hematuria. In such cases, 0.5 c.c. each of the $ZnSO_4$ and NaoH solutions are added to the 1 or 2 c.c. samples of urine in a volumetric flask, the mixture then made up to volume with water and a sufficient amount filtered.

2. Oxidation of Diodrast-Iodine to Iodate: 0.2 c.c. of 85 per cent $H3PO_4$ is added to 10 c.c. of plasma filtrate or diluted urine in a colorimeter absorption tube. One c.c. of bromine water is added and the mixture shaken until homogenous. The tube is then placed in a boiling water bath for three minutes, when it is rapidly cooled to room temperature in an ice bath. The wall of the tube is then carefully dried by wiping with a soft towel, and 1 c.c. of 10 per cent sodium formate added. The solutions are mixed by shaking and then allowed to stand 20 to 30 minutes at room temperature.

3. Measurement of Color Density: The clarity of the mixture before addition of KI permits determination of the individual "center-settings" of each tube, thus correcting for inaccuracies in the calibration of individual tubes and permitting the use of tubes which have become too scratched or worn for other uses. The "center-setting" is determined for each tube in the series, using the appropriate color filters. One drop of alkaline KI is then added, the "center-setting" is appropriately adjusted, and the reading is made at exactly two minutes.

Light filter No. 400 is suitable for the determination of plasma "blank" and of plasma diodrast-iodine concentration during clearance periods. Filter No. 440 is ordinarily used for the determination of diodrast-iodine in urine dilutions and No. 490 for the concentrations in plasma and urine which obtain in determination of Tm_D.

Calculation.—The determination of diodrast-iodine concentration from

galvanometer readings is made by reference to a calibration curve from the preparation either of iodate solutions or from dilutions of 35 per cent diodrast solution treated with all reagents exactly as described. The separately measured plasma "blank" should be subtracted from the observed plasma concentration, and the result multiplied by the dilution factor (11); thus (0.175 to 0.002) 11.0 = 1.925 mg. per 100 c.c. of plasma, where 0.0175 is the apparent diodrast-iodine content of the 10 c.c. of unknown plasma filtrate and 0.002 the value of the plasma "blank."

The high dilutions of urine used obviate any appreciable error from urinary "blank."

Results.—The mean recovery in 34 determinations of diodrast-iodine added to human plasma was 100 per cent. The range of recovery in this series varied from 97.5 to 102 per cent. The concentrations used ranged from 1.9 to 66 mg. per 100 c.c. of plasma.

We found the method particularly useful because: (a) There is the convenience and safety of bromine water and sodium formate in contrast, respectively, with bromine and phenol reagents; (b) the separate determination of "center-setting" for each tube obviates errors due to differences between individual tubes, such as result from etching or scratches and permits the use of tubes, which would otherwise be discarded; and (c) the use of 10 c.c. of plasma filtrate in a final volume of 12.2 c.c. yields a color density from 1.0 mg. per 100 c.c. plasma diodrast-iodine which, using filter No. 400, reaches at about the center of the galvanometer. The use of a special filter for determination of low concentrations of iodate-iodine is thus avoided.

The use of "Duponol PC" was practiced because it was found that its detergent action made it possible to obtain full recovery of plasma diodrast in zinc filtrates in which the plasma had been diluted only 10 or 11 times, whereas only 90 to 95 per cent was recovered in these filtrates in the absence of "Duponol PC," when it was added in large excess or when a series of other detergents were tried. Full recovery of diodrast-iodine, however, may be obtained from plasma in zinc filtrates without the use of the detergent when the plasma is 15 times diluted.[3] We have found the more concentrated filtrates advantageous, and therefore retain the use of "Duponol PC." Probably some other application in clinical chemistry of this action of detergents will be found.

SUMMARY

A convenient method is described for determination of diodrast-iodine in urine dilutions or plasma filtrates. The method depends upon the detergent action of "Duponol PC" for full extraction of diodrast from plasma: the diodrast-iodine of the plasma filtrates is then oxidized with bromine water and the excess of bromine decomposed by adding sodium formate. The iodate-iodine content of the samples is determined photocolorimetrically by the method of Flox, Pitesky, and Alving.[3]

MEDICAL ILLUSTRATION

COLORING AND APPLYING FACIAL PROSTHESES*

CAPTAIN CARL DAME CLARKE, SANATORY CORPS, ARMY OF THE UNITED STATES
WASHINGTON, D. C.

IN CONSIDERING the color result of a final prosthesis it must be realized that there are seven distinct steps that can be used in color work alone to obtain the finished product. All of these are not necessary in every instance, but each step is worthy of consideration. The procedure begins with the latex mix and does not end until cosmetics are applied to the prosthesis when it is in place on the patient. The steps taken to produce the color effect are as follows:

1. Counteracting the natural yellow color of rubber and its tendency to darken.
2. The addition of water-soluble pigments and dyes to the latex mix to produce a basic monochrome skin color suitable to the individual patient.
3. Blended color effects on the dried rubber prosthesis achieved with oil-soluble dyes.
4. Detail effects produced with alcohol-soluble dyes.
5. Placing of hair, glass eyes, and fingernails in the rubber cast.
6. Highlighting or lacquering the surface.
7. The application of cosmetics.

These steps are of sufficient importance to require a detailed description of each.

1. *Counteracting the Natural Yellow Color of Rubber.*—Unfilled rubber turns dark on prolonged exposure to sunlight. It assumes a yellow cast which varies from light cream to raw umber. Steps to forestall this change must be taken while the rubber is in the latex state. Zinc oxide (a thickening agent) and clay or chemical fillers should be added. The zinc oxide should not exceed 2 per cent in vulcanized latex or 4 per cent in unvulcanized latex; otherwise the final prosthesis may crack. This cracking can occur even when the prosthesis is soft and pliable. An excess of zinc oxide would cause the prosthesis to become so opaque that it would not possess the translucency of normal Caucasian skin.

In addition to the zinc oxide, clay fillers can be added to prevent the rubber from becoming too dark. The clay fillers should not exceed 10 per cent or the translucency will be lost. In fact, if the rubber contains both zinc oxide (2 per cent) and clay filler (10 per cent), the prosthesis may lack the translucency of normal Caucasian skin. The proportions should invariably be less than the percentages mentioned. The mixture is balanced to suit specific types of skins. It is often better to make up stock solutions of the rubber

*From the Department of Moulage and Prosthetics, Army Medical Museum.
Received for publication, July 9, 1943.

latex containing different percentages of clay filler. I believe the clay fillers are more suitable than zinc oxide for this purpose. If clay is used various stock solutions of latex can be prepared, each having the proper basic colors incorporated, and each being slightly different from the other. A dried sample from each lot may be attached to the neck of the bottle. These samples are placed next to the patient's skin to determine which solution is most suitable

Fig. 1.—The front view of a patient requiring a prosthesis.

for making the final prosthesis. If zinc oxide is used instead of clay to prevent darkening, the stock solution may in time coagulate in the bottle and become unfit for further use. When zinc oxide is chosen, it must be incorporated as a thin water paste into the latex just before it is poured into the mold. Stock solutions containing a small amount of zinc oxide that are kept for long periods of time become so thick that it is difficult to pour them into

molds having small openings. If the stock solution is diluted with water, it continues to sink in the mold because the plaster absorbs the water, and air pockets will likely form in the cast. These may be corrected by refilling the mold as the solution sinks in the opening. Some stock solutions containing zinc oxide thicken considerably in twenty-four hours. Although this may be an advantage when it is necessary to build up a coagulum deposit, as on agar molds of hands, it is a disadvantage in molds that have small openings as in a prosthesis of the ear or nose.

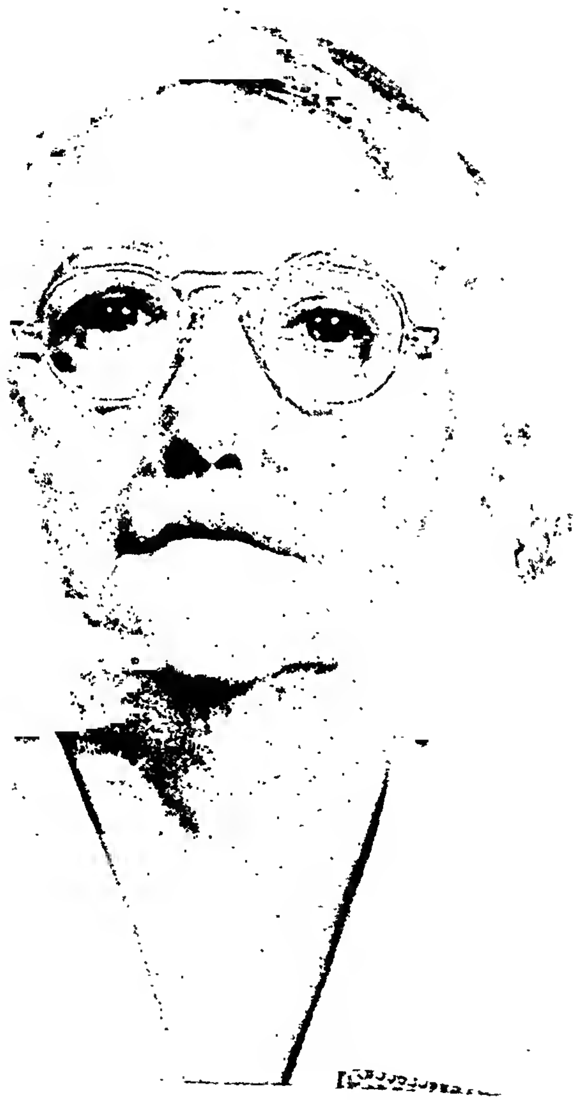

Fig. 2.—The prosthetic nose in place.

It seldom takes more than 100 c.c. of latex mixture to make the average prosthesis of an ear or nose. Therefore, the 2 to 4 per cent of zinc oxide required for this quantity can be added with an eye dropper from a stock

solution of zinc oxide ground in water to a thin paste or viscous liquid. For example, there are about 15 drops to 1 c.c.; therefore, 30 drops or 2 c.c. of this water dispersion can be added to 100 c.c. of the rubber mixture to get the proper mix for a prosthesis. This is only a rough method of figuring but it is sufficiently accurate for the purpose. If the rubber mixture contains the clay filler, the zinc oxide content can be reduced or eliminated.

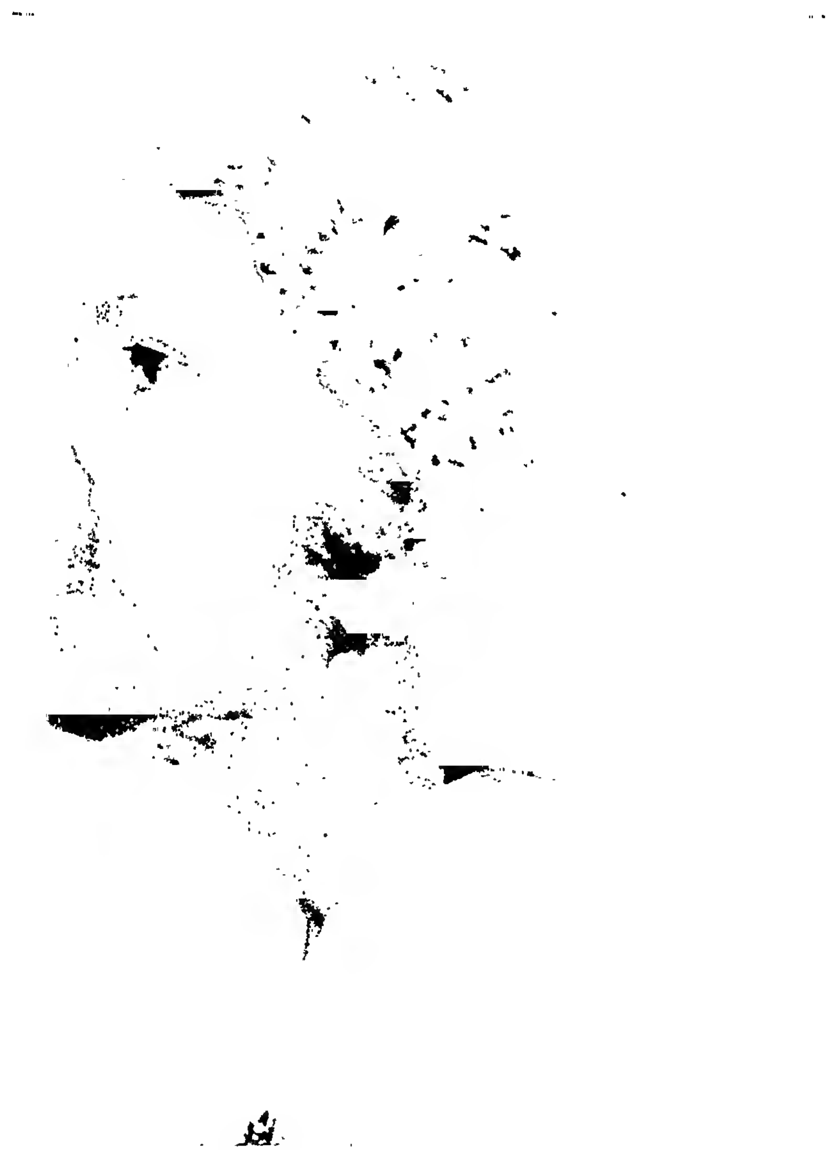

Fig. 3.—The side view of the same patient without the prosthesis.

2. *The Monochrome Base Color.*—Usually a monochrome base color is added to the latex mix to give it a general tint similar to that of the patient who is to wear the prosthetic appliance. As noted before, it is customary to have on hand various stock solutions of slightly different flesh colors because each patient's skin tones vary. This is particularly true among Negroes. As a

rule, six stock solutions suffice for Caucasians. Eight should be enough for Negroes. When a skin tone is between the color of two stock solutions, the proper color may be made by mixing the two. A dried sample of each skin tone should be attached to the neck of each bottle of stock solution, since the dried latex is different in color from the liquid latex. It is invariably darker. These samples are placed next to the skin to match the color. The prosthetist generally chooses one a shade lighter than the patient's color because other color mediums are added which eventually create the desired effect. Furthermore, all rubber prostheses tend to darken on prolonged exposure to sunlight. From time to time, over a period of months and years, it may become necessary to remake a prosthesis, and for this reason the mold of each patient should be filed away for future use.

To obtain the stock monochrome solutions previously mentioned, color in the form of pigments or dyes is added to the latex filler mixture. These pigments and dyes must be confined to certain restrictions. For example, they should not have an acid reaction to litmus paper. If they do, they will coagulate the latex into a mass or into isolated particles. They should contain no copper. If copper is present, even in small quantities, resinification of the rubber will follow. If opaque pigments are used to excess, the translucency is destroyed in the resulting prosthesis. Translucency is essential to naturalness, and for this reason transparent dyes are usually employed. Unfortunately, the average dyes available for rubber are not as permanent as pigments. Pigments are ground with water before being incorporated. Dyes are added to water until translucent solutions without any sediment are formed before incorporation. A considerably larger quantity of pigments than dyes is necessary to obtain the desired shade. When adding both pigment and dye solutions to small quantities of latex, it is advisable to use an eye dropper. The color is added a drop at a time while stirring the mixture.

In considering the brownish-red tones of Negroid skin, one may say that all three primary colors are often employed to obtain the desired effect. For this reason pigments and dyes of various shades are listed.

The following color ingredients are suitable for latex mixes:

Lithopone
Sulfide of antimony (if free from calcium sulfate)
Inactive carbon or lamp blacks, ivory black or the like
Green chromium oxide
Natural red iron oxide
Organic colors, if available in powdered or paste form

Among the water-soluble colors manufactured by E I Du Pont de Nemours & Company are the following: Pontamine fast dyes which are compatible with rubber latex and are to a great degree permanent.

Pink BL
Brown 2 RL
Blue 4 GLN
Red 8 BNL
Blue SRL
Gray BL
Orange 2 GL
Yellow NNL

These dyes are in powder form. About 20 Gm. of the powder are added to 200 c.c. of water. This mixture is added drop by drop to small quantities of rubber. The concentration of dye in water can be stronger for Negroid skin. It is difficult to give specific amounts of dye to be added to water because each person's skin varies in color, and the concentration of dye to water may vary. The prosthetist must depend on his sense of color to determine the amount of dye to be added to each latex mix or to a stock solution.

Fig. 4.—A side view of the same patient with the nose in place.

Most dye manufacturers list dyes that are suitable for incorporating with rubber. These manufacturers are listed in the Chemical Buyers' Guide Book,* which is practically indispensable to the prosthetist.

*Chemical Buyers' Guide Book, Chemical Industries, 522 Fifth Avenue, New York City.

In any event, the monochrome tint applied to the latex mix is kept somewhat lighter than is desired for the finished prosthesis, because additional oil-soluble color will be added later.

After the desired tint is chosen the mold is poured; the cast is dried in the mold and removed. The seam lines are trimmed with instruments heated over a Bunsen burner. Often a syruplike substance is thus produced. This is burnt resinified rubber and may be removed with a small piece of cloth dampened with turpentine. In fact, the prosthesis can be given a rather vigorous cleaning with the turpentine cloth. It serves to remove the tiny imperfections caused by the smallest air bubbles in the mold. The larger positive impressions of air bubbles must be cut away. The turpentine may cause the rubber cast to swell, but this will rectify as the cast dries. When one really masters the use of the tools and a knowledge of the temperature at which to use them, seam lines may be cut away with the hot tool without resinifying the rubber. Moreover, skin detail can be replaced and defects in casting removed or repaired without damage to the surface. Although depressions caused by faulty casting can be modeled out by the addition of small amounts of latex to the cast, this procedure is not always successful. It is generally better to remake the cast. The rubber cast should be washed thoroughly in soap and water after it is cleaned with turpentine.

When the prosthesis has been trimmed carefully and all defects have been corrected, it is time to use the oil-soluble dyes.

3. *Blended Shading With Oil-Soluble Dyes.*—Unvulcanized rubber is soluble in carbon disulfide with 5 per cent absolute alcohol, benzene (benzol), chloroform, benzine and oil of turpentine. Vulcanized rubber, however, only swells in these solvents, and after prolonged soaking it loses its strength to a point where it crumbles readily. Benzine being more volatile than turpentine has a quicker swelling action on the vulcanized rubber than turpentine. If oil-soluble dyes are mixed with these rubber solvents, a coloring medium is produced that will sink readily into the rubber and give permanent tints. It should be realized, however, that the dye continues to bleed into the rubber and becomes less intense. By means of this change the prosthetist is able to obtain more lifelike blended color effects on a monochrome prosthesis. In other words, skin is not a monochrome, but is made up of delicately blended areas of different shades of the same color or different colors. The same effect cannot be obtained with pigments because these are composed of microscopic particles of opaque matter which do not sink or bleed into the rubber but lie on the surface. Even if perfect blending with pigments were possible, the color would in a short time wash from the surface of the prosthesis and expose the monochrome-tinted rubber.

An oil-soluble dye applied in the same manner sinks into the rubber, and the prosthesis may be washed or even scrubbed immediately afterward. As time progresses the dye blends or bleeds further into the rubber and becomes more uniformly distributed or thoroughly blended with other shades. For this reason the prosthesis is generally colored more deeply than is desired for immediate use. The complete blending may require a few days. After several experiments, however, the worker can anticipate the effect that time will produce. It is assumed that once the solvent has evaporated from the rubber the blending will cease.

The difference between pigments and dyes can readily be detected with a microscope. For example, samples of a red pigment and a red dye are placed on a microscopic slide and studied through transmitted light. The pigments will appear as black specks and the dye will still appear red on the slide.

Fig. 5.—A side view of a patient requiring a prosthetic ear.

Oil-soluble dyes serve their most important purpose in obtaining pink-blended flushlike effects on the cheeks, lips, tips and ala of the nose, and knuckles, and blue effects of veins that lie beneath the skin.

These results are obtained by preparing a mixture of one part of turpentine and one part of benzine as a medium. Into 50 c.c. of this mixture are dissolved 10 Gm. of the oil-soluble dye. This will produce a heavily concentrated dye mixture which may be considered a stock solution. Before it is

used a drop or two of the solution is added to a few drops of the benzine-turpentine mixture. The diluted mixture is applied with a brush to tint the prosthesis at the desired places. It is advisable to try to blend at the time the color is applied, but it should be realized that the resulting blended effect takes place automatically by bleeding rather than by the artistic skill of the worker. As the colors bleed they become lighter; therefore, the tints are applied more intensely than desired in the finished prosthesis. After applying the oil-soluble dyes, the prosthesis may be left to stand or it may be washed immediately with soap and water to test the permanency of the dyes employed. If the right dyes are used and the work done properly, it will be impossible to wash off the dyes.

The following is a list of oil-soluble dyes suitable for this purpose which are manufactured by Du Pont:

Anthraquinone Blue AB Base
Anthraquinone Blue SKY Base
Anthraquinone Green G Base
Anthraquinone Iris R Base
Oil Red
Oil Black BG
Oil Brown N
Oil Yellow N
Oil Yellow
Oil Fast Yellow EG

4. *Alcohol-Soluble Dyes.*—The alcohol-soluble dyes have their place in prosthetic work, but they are not used to the same extent as those that are oil-soluble. The stock solutions of these dyes are made up in the same manner; that is, 10 Gm. of dye are added to 50 c.c. of alcohol. The intensity of the dye can be reduced as it is used by adding a few drops of dye solution to the alcohol until the desired shade is obtained. The diluted solution is applied to the prosthesis with soft brushes. Blended surface effects can be obtained. These dyes remain where they are placed and do not bleed into the rubber. In some cases it is desirable to put a thin coat of matte lacquer over the finished prosthesis, which in turn makes the alcohol-soluble dyes adhere more readily to the rubber surface. This will be discussed more fully later.

The following alcohol-soluble dyes manufactured by Du Pont are suitable for use on rubber:

Luxol Fast Red BB
Luxol Fast Red B
Luxol Fast Scarlet C

5. *Applying Hair, Artificial Eyes, and Fingernails.*—For the sake of naturalness it is sometimes desirable to imbed hair into the rubber cast. Each hair is usually inserted separately with a needle. The tip of the eye end of a small needle is filed until it is open at the end. Then the pointed end of the needle is fixed into a small piece of wood which serves as a handle. To insert the hair a pointed needle is used to pierce the rubber and the forked end of the prepared needle is used to straddle the end of the hair over the pierced rubber.

By applying pressure to the hair with the forked needle over the hair, it is forced into the previously formed hole. The strength of the rubber closing over the hair is generally sufficient to hold it in place. If the hair is placed into a hollow rubber cast, such as a masculine hand filled with a microcrystalline wax core, however, the wax will give additional adhesion in holding the hair in place.

Fig. 6.—The same patient with the ear in place.

A large area of hair as, for example, a mustache, may be applied to a male patient to hide joining lines where a prosthetic nose and lip connect to the face.

The process of setting hairs in a foundation of gauze, lace, or woven stiff silk is known as *ventilating*. The needles employed for the purpose are *ventilating needles*. These have front hooks of varying sizes, ranging from small to

large. Small ones are used to thread one or two hairs and the larger ones for more strands.

Fig. 7.—The front view of the patient without the prosthesis.

If the prosthetist does not wish to attempt this branch of the art, a professional wigmaker can supply artificial mustaches to match natural hair. Indeed, he can make them from the patient's own hair. Eyebrows may be made in the same way. Although this manner of making mustaches and eyebrows is not the most successful, it may serve the purpose. The most naturalistic eyebrows and eyelashes can be obtained from cadavers. These are cut away, tanned. and softened before use. After removal of the brow or lash the fat of the skin is dissolved out in benzine. The skin is then bleached in hydrogen peroxide or a hyperchlorate solution. It should be noted that the

peroxide will also bleach the hair and this will subsequently have to be dyed to the desired shade. The skin is then treated with tannic acid and finally softened in a weak solution of glycerin or a similar agent. Such natural eyebrows and lashes are easily obtainable by the physician and prosthetist having connection with a school of medicine.

Fig. 8.—A front view of the same patient with the ear in place.

Artificial eyelashes which may be purchased from cosmetic stores and costumers and attached to the human eyelids in order to enhance the beauty of the wearer are not suitable for prostheses because they are so long they give an unnatural appearance. If they are trimmed shorter the ends of the hairs are blunt. Natural eyelashes are tapered to pointed ends. The blunt hairs are obvious on the prosthesis.

The gauze or natural eyebrows are attached to the surface of the rubber with the same latex mix that is used to make the prosthesis. The latex mix may be applied directly to the gauze or leatherized skin with a brush, after which the mustache or eyebrow is set in place. A hypodermic syringe with a large needle may also be used to inject additional latex between the hairs on top of the gauze. By using the syringe and needle the latex can be kept from soiling the hairs.

In order to obtain the best adhesion of the latex to the set rubber, the prosthesis should first be wiped off with a cloth dipped in alcohol. This removes grease and foreign matter that may prevent the gauze or leather from sticking. It is also more natural to insert a few stray hairs into the rubber around the mustache or eyebrow.

Artificial eyes may be purchased from the larger optical and taxidermal supply stores. Those furnished by the taxidermist are globe-shaped, whereas those supplied by the optical stores are shell-shaped. The shell-shaped eyes are more expensive but better to use. The globe-shaped eyes, however, may be cut to size with a three-cornered file. In any event, the artificial eye is first matched to the real eye of the patient and fitted into the wax pattern. The wax is fitted to the patient to be sure the eye will look natural. A plaster mold is made over the eye and wax pattern. Before the rubber latex is poured into the mold the eye must be removed from the wax and replaced by itself into the mold. It may be held temporarily in its original place by a small piece of sticky wax. The mold is then closed and the latex mix poured. After the set rubber is removed, it may be necessary to trim some of the rubber where it joins the eye. This, of course, is done with hot tools. If the patient has one good eye it is logical that the glass eye incased in a rubber prosthesis will not move with the natural eye. Unfortunately, this cannot be helped but it will be less noticeable if the patient wears eyeglasses with one dark lens and one clear lens, or with two slightly tinted lenses.

If a prosthetic hand is well done it is seldom necessary to use artificial fingernails, especially with hands of men. It is advisable, however, to apply natural cellulose acetate fingernail lacquer to the rubber nails. The average woman prefers artificial nails which may be purchased from cosmeticians and five-and-ten cent stores. They are applied by simply trimming them to fit the particular rubber fingers and then sealed in place with cellulose acetate or polyvynl acetate cement. Some natural fingernail lacquers also may be used for affixing the artificial nail to the rubber fingers.

6. *Highlighting or Lacquering the Surface.*—It is not always necessary to lacquer the surface of a rubber prosthesis, but frequently this is desirable, especially to cover lips and eyelids. The lacquer on rubber often makes the rubber more receptive to cosmetics; because the rubber surface causes a "drag" on the fingers and brushes that are used in applying make-up. The wearer of a prosthesis must learn to use the lacquer as well as cosmetics. If he gets a better effect with lacquer he must clean the cosmetics and old lacquer from the prosthesis with alcohol after the prosthesis is removed. He then applies an extremely thin coat of matte lacquer before retiring for the night. The next morning the lacquer is thoroughly dry and the prosthesis is

ready for reapplying and is receptive to the make-up. Since the lacquer is alcohol-soluble, the adhesive for holding the prosthesis in place, which is also alcohol-soluble, must be applied with care to the reverse side to prevent mixing and the formation of a gum deposit on the edges. Although the lacquer is not essential and is seldom used by masculine patients, it has its place in creating special effects. It should also be realized that lacquer will eventually wash from the surface; it should not be considered as a permanent part of the prosthesis. If the prosthesis lacks translucency a matte lacquer will create an effect of translucency. A primary use of lacquer is to set or hold any surface coloring with alcohol-soluble dyes and to make the surface more receptive to the application of cosmetics, as previously mentioned. It is well known that many face creams contain an oil or grease in one form or another. These oils and greases readily attack and deteriorate rubber if used in excess. The prosthetist can use cosmetics that have no oil or small amounts of oil or grease in them, or he can make the surface of the prosthesis impervious to the action of cosmetics. *Face creams and lotions containing stearic acid may be used as a powder base, because the stearic acid does not readily attack the rubber. Therefore, vanishing creams may be used, whereas cold creams should be omitted. This subject will be discussed more fully under Cosmetics.*

If lacquer is used it should be alcohol-soluble and kept quite thin. Most lacquers can be diluted with acetone; others may be diluted with alcohol to acquire this thin consistency. This applies particularly to the polyvinyl acetate lacquers. A formula most suitable for this purpose is as follows:

	Parts by weight
Ethyl alcohol	700 Gm.
Ethylene dichloride	200 Gm.
Amyl acetate	80 Gm.
Castor oil	20 Gm.
Polyvynl acetate	100 Gm.

The liquids are mixed together and the polyvynl acetate crystals are added. The container is shaken from time to time until the polyvynl acetate is dissolved completely.

Commercial lacquers are invariably too brittle on drying for application to rubber, which undergoes considerable bending and stretching. It may also be necessary to add a small amount of castor oil to the commercial lacquer to make it more plastic on drying. If the lacquer cracks or develops other defects that make it undesirable, it may be removed from the prosthesis with a cloth dampened with alcohol. Lacquer that is not alcohol-soluble may be removed with a cloth dampened with acetone or amyl acetate.

7. *Cosmetics.*—As in the case of lacquers, cosmetics are not absolutely essential to a well-prepared and colored prosthesis. Because of the darkening effect of sunlight on rubber and the changing of skin tints as a result of the various seasons, however, cosmetics may be employed to counteract these gradual differences. Furthermore, cosmetic pastes are used to fill *join lines* to make them invisible. *Join lines* result where the prosthesis meets the natural

skin. In any event, cosmetics should be used sparingly. Any semblance to stage make-up should definitely be avoided. Opaque pastes and lotions should not be used, or the translucency of the rubber and skin will be lost and produce an unnatural appearance. The following general remarks on the application of prostheses and make-up to the face should be studied carefully. It should be remembered that there are a variety of facial prostheses, such as eye sockets, noses, ears, and depressions or scar casts.

1. The face is washed with a mild soap. If the patient has a tendency toward oily skin, an astringent should be used after washing. Practically any astringent is suitable for this purpose. A satisfactory one may be prepared as follows:

Alcohol	1,000 c.c.
Menthol	4 Gm.
Glycerin	50 c.c.
Water	1,300 c.c.
Perfume	q.s.
Color (vegetable dye)	q.s.

The menthol is dissolved in the alcohol and the other ingredients are added in the order mentioned.

2. The adhesive is placed on the side of the prosthesis that comes in contact with the skin surfaces. It should not extend to the front or back beyond the area that is made to fit the face. I have found the following formula suitable for this purpose:

Gum mastic or colophony	175 Gm.
Ether	200 c.c.
Alcohol	200 c.c.
Castor oil	10 c.c.

The gum mastic is placed in a bottle; the castor oil is mixed with the alcohol and then added to the gum mastic. Finally, the ether is poured in and the bottle is shaken well. In a day or so the gum mastic will be dissolved completely. Impurities in the mastic, such as dirt or pieces of bark, settle to the bottom. The clear liquid is poured off and put into smaller bottles to be supplied to the patient. The gum mastic in this formula is the adhesive agent. The ether is for quick drying and the alcohol is for slower drying. Some patients prefer to use ether as the solvent for gum mastic, because they can put the prosthesis in place the moment the adhesive is applied. Others prefer to use alcohol only, since it gives them a minute or so to wait before putting the prosthesis in place. The castor oil is used to prevent the mastic from crystalizing on drying. Colophony (rosin) can be substituted for the gum mastic. I know of two cases that developed a rash from the use of gum mastic. In such a case another gum should be substituted.

3. After the prosthesis is in place a pastelike putty should be applied over the join line where the prosthesis comes in contact with the human skin. This is particularly necessary for noses and eye sockets, but is not essential in prosthetic hands. The putty is used sparingly on small artificial portions of

the ear to cover the join line where the lobe or top curvature meets the natural ear. If an entire ear is made the join line can be planned at the least conspicuous place next to the head. A join line in the front of the ear should be made invisible.

A theatrical nose putty can be purchased from drug stores. This material is difficult to use, however. A far more satisfactory product can be prepared as follows:

Be Square special wax, 160 to 165 m.p., amber (Bereco Oil Co., Tulsa, Okla.)	20 Gm.
Mineral oil	5 c.c.
Rosin (water white)	20 Gm.
Talc	20 Gm.
Red color (oil-soluble)	q.s.
Perfume (oil or alcohol-soluble)	q.s.

The mineral oil and wax are melted together; the rosin is then added and the mixture stirred over a low fire until completely melted. It is removed from the fire and the talc added. The mixture is stirred until cold. If too sticky more talc is added while cold, and the mixture is kneaded like dough until it will not stick to the fingers. A drop of diluted oil-soluble red color and a drop of perfume are added and the kneading is continued until the correct color is obtained. The wax gives plasticity to the composition, and the rosin causes adhesiveness. The mineral oil is used to overcome the dryness produced by the talc and to improve the pliability. The talc counteracts the extreme stickiness of the mixture and reduces the excess translucency. This putty should be of a consistency that bends readily without cracking as the face assumes different expressions. For winter use, a few additional drops of mineral oil may be added. The color should be of a shade and quantity to suit the individual. This is of no great consequence, however, since a stock supply can be made up without the color. The color can be added to a small amount of the stock supply while kneading the putty in the fingers. From time to time the putty is held next to the patient's skin for matching. When the correct tint is reached the putty is given to the patient for use.

This mixture is employed to cover join lines in the following manner. The fingers are dipped in water to keep the putty from sticking to them. A small piece is rolled between the fingertips until it is cylindrical and about the size of a toothpick. This is laid over the join line and pressed into place with a wet finger. It is then smoothed out until the prosthesis blends with the face and the join line disappears.

4. After the join line is covered a skin lotion or vanishing cream may be used as a powder base to cover both the prosthesis and the face. This should not be of an oily nature and should be applied sparingly. A small amount is dappled on the forehead, cheeks, and chin, then blended with the fingertips into the skin and prosthesis until the lotion disappears.

The following formulas devised by the Atlas Powder Company are most satisfactory for use with prostheses for powder bases, vanishing cream, skin lotion, and similar preparations:

	Ingredients	Formulas 1	2	3	4
A.	1. Arlex	3.0	8.0	5.0	2.5
	2. Potassium carbonate	0.7		0.7	
	3. Potassium hydroxide		1.0		
	4. Triethanolamine				1.7
	5. Water	76.4	64.1	45.1	70.9
	6. Preservative	q.s.	q.s.	q.s.	q.s.
	7. Stearic acid	15.0	20.0	10.0	3.5
	8 Lanolin	0.5	1.5	0.5	2.0
	9. Mineral oil	2.0	2.0	35.3	15.0
B.	10. Mannitan Monooleate (Atlas G-954)	2.0	1.0	1.0	2.0
	11. Mannitan Monostearate (Atlas G-908)			2.0	2.0
	12. Spermaceti		2.0		
C.	13. Perfume	0.4	0.4	0.4	0.4

METHOD OF MANUFACTURE

Warm A and B separately to 75 to 80° C.
Add B and A slowly and with thorough agitation.
Add C at 50° C.
Note: Stir No. 1 and No. 2 intermittently, and when body has increased, turn over by hand. No. 1 cream may be poured directly into jars at 58° C.
No. 4 cream must be passed through colloid mill or homogenizer while still fluid.
No. 3 cream should be stirred until cold, set aside over night, and remixed the following morning.

No. 1, Vanishing Cream
No. 2, Hand Cream
No. 3, All Purpose Cream
No. 4, Liquid Cream

MODIFICATIONS

For modification of the above formulas the following will serve as guides:

Foundation Cream.—Formula No. 2. Add 2 per cent titanium dioxide.

Powder Cream.—Formula No. 2. Add 5 per cent titanium dioxide and color lakes.

Emollient Skin Cream.—Formula No. 3. Increase lanolin to 5 per cent or as required.

Liquid Cleanser.—Formula No. 4.

Hand Lotion.—Formula No. 4. Reduce mineral oil to not over 5 per cent, increasing water by like percentage.

Liquid Powder Base.—Formula No. 4. Reduce mineral oil to 5 per cent as above.

5. After the powder base is applied and dried, moist rouge or powder cake rouge may be blended into both the skin and prosthesis at the proper places. The moist or cream rouge serves best for this purpose because the dry cake rouge does not spread evenly over rough or hairy skin and enlarged pores Some rouges have a tendency to permanently dye the rubber. If the rouge

used cannot be removed from the prosthesis with alcohol it should not be considered for prosthetic work. Rouge also can be used to good advantage on the ala of a prosthetic nose or the top curvature and lobe of a prosthetic ear if the prosthesis lacks color at these points or if fugitive colors were used in making the prosthesis. The rouge should be applied sparingly and blended with the fingertips. In making up a prosthesis the tendency should always be toward naturalness without in any way leaning toward the theatrical. The main object is to prevent a "made-up" appearance and to avoid attracting undue attention to the face.

6. Any face powder of suitable shade and texture can be used over a proper powder base. It should be dusted on lightly and blended over the whole with a soft powder puff. It, too, should be applied sparingly to prevent an opaque cast to both natural and artificial skin. Powder applied to the skin has a tendency to kill the natural sheen and high lights. Often it is desirable to restore the natural qualities of the skin. A cold moist towel gently pressed against the face and prosthesis will set the powder and at the same time restore natural skin characteristics. This is especially desirable for a male patient. The powder aids greatly in hiding properly filled join lines.

7. Lipsticks or paste can be used in the usual manner over both rubber and natural lips, but should not be used in excess, since the grease content may cause the rubber to deteriorate unless it is lacquered. Indelible lipsticks should be avoided because they stain the rubber to such an extent that the color cannot be removed. It is good practice to test a lipstick on the back of a prosthesis to see if it can be removed properly before using it on the lips.

8. Eyebrow pencils can be used if desired on rubber prosthesis with hair. Such prostheses should be made to withstand washing with mild soap and water and an occasional cleaning and disinfecting with alcohol.

9. Brilliantine and similar hair preparations can be applied with a tooth or mascara brush on the hair of a prosthesis. Such mixtures should be used with care and very sparingly, however. An excess of oil in the artificial hair collects dust and foreign particles. This necessitates frequent cleaning, resulting in premature deterioration of the artificial hair, and replacement becomes necessary.

Editorial Announcement

Previously it has been customary to end the volumes of THE JOURNAL OF LABORATORY AND CLINICAL MEDICINE with the September issue. A change has been made, however, by which the future volumes will conform to the calendar year, beginning with the January issue and ending with that of December. The present volume 28 will, therefore, continue through the December number, and the index which has been omitted from this number will appear instead in that issue.

Editor.

CLINICAL AND EXPERIMENTAL

THE PHYSICS OF SOUND WITH PARTICULAR RELATION TO EXAMINATION OF THE PATIENT

Earle M. Chapman, M.D.,* and Avram Goldstein,† Boston, Mass.

INTRODUCTION

THE application of the principles of physics to the examination of the patient was introduced by Skoda and Hoppe[1] 100 years ago. Since that time their ideas have been amplified and experimentally verified.[2] We believe, however, this knowledge has been neglected in current teaching and for this reason we are presenting these ideas, not original, which are necessary for the student's appreciation of the fundamentals of physical diagnosis. Montgomery and Eckhardt's[3] admirable work clarified the physics of breath sounds, and herein we hope to accomplish the same for the phenomena of percussion and tactile fremitus. For clarity we shall present this material in three steps:

1. Sound waves—four qualities: intensity, pitch, duration, and quality (timbre).
2. Sound waves—four fates: diffusion, absorption, reflection, and resonance.
3. Application of the physical principles to tactile phenomena and percussion.

I

Sound is the result of rhythmic vibrations of the air striking upon the ear. The range of audible sound is from 16 to 36,000 vibrations per second. The range of musical tones is from 40 to 4,000. Sound waves can be represented diagrammatically to show the *four qualities* of sound: intensity, pitch, duration, and quality, as follows:

*Instructor in Medicine, Harvard University.
†Third Year Student, Harvard Medical School.
Received for publication, February 1, 1943.

1. *Intensity.*—In this we are concerned with the *amplitude* of the vibrations or the total excursion of the mass of air moved. In Fig. 1 wave length is the same in 1A and 1B, but amplitude differs. The tones shown are identical, but since 1A is greater in intensity than 1B it is a louder note.

2. *Pitch.*—In this we are concerned with *frequency* (vibrations per second) that differentiates one pitch from another. A deep note is one of low frequency, Fig. 1, 2A; a higher note is one of many vibrations per second, 2B.

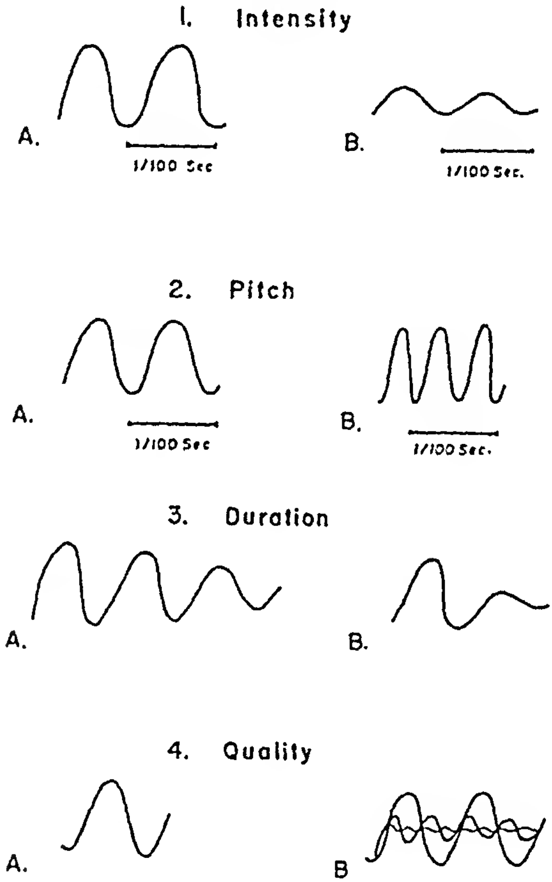

Fig. 1.

3. *Duration.*—All sounds diminish in intensity with time; they "die out." In Figs. 1 and 3, the tones are identical except that the duration of A is greater than that of B. Once the initial disturbance creating the sound no longer exists, the sound will persist for a shorter or longer time depending on a number of factors. The chief factor determining duration is the "sympathetic vibration" of a large mass of elastic material, usually air, which reinforces the original sound. For example, the plucking of a violin string alone produces a short sound, but with this string stretched over the sounding box, a large mass of air is set into vibration and a sustained tone results.

4. *Quality (timbre).*—The concept of quality is exemplified by the dissimilar tones of a violin, a voice, and a flute, all sounding the same note at the same intensity for the same length of time. Quality depends upon the presence or absence of overtones. When a violin string or a column of air vibrates at a certain frequency, the whole string or air column is in vibration as a unit.

The string or air column may vibrate in halves, giving a note of twice the frequency; or in thirds, fourths, and so on, and these various notes are heard superimposed upon the fundamental tone. What we usually call "richness" of tone is the presence of many overtones, all bearing a direct harmonic relationship to the fundamental, that is, all simple multiples of the fundamental. In Figs. 1 and 4, A is a pure tone, while B is rich in overtones.

II

Of what importance are these concepts when one is studying sound traveling through the body tissues? In tactile fremitus the vibrations originate within the body and travel outward to the palpating hands of the examiner; in percussion some of the sound waves travel from the percussing finger toward the interior of the body, where they are amplified or not, depending upon the properties of the substances underlying their point of entry; in auscultation the sounds arise within body tissues and travel toward the surface and the observer's ear.

Four fates lie ahead of such sound waves traveling through body tissues.

1. *Diffusion.*—The vibrations may set into motion tissues or air lateral to their direction of motion. Such lateral vibrations never reach the hand or ear of the examiner, since they gradually subside through diffusion in several directions.

2. *Absorption.*—This is the complete disappearance of sound vibrations, the energy of which is transformed into heat in the substance in which the sounds are damped out. Absorption must really be considered together with its opposite, transmission, since the properties of the medium determine whether sound will be transmitted or absorbed. A very elastic substance like air enclosed in a space with elastic walls (lung) transmits most of the sound waves passing through it. On the other hand very inelastic material (soft tissue, muscle) absorbes most of the vibrations.

3. *Reflections.*—The use of this term in connection with sound waves is similar to its use in optics. For reflection of sound waves to occur there must be two media meeting at an interface; reflection is favored by a large difference in density between the media. The best example of this is pleural fluid, which acts as a reflecting layer so that the vibrations of fremitus cannot reach the palpating hand nor can those of the percussion blow reach the underlying lung.

4. *Resonance.*—This term is used here to describe a physical principle, and not in its more specific meaning as one of the percussion sounds. The principle of resonance is that of tone reinforcement (sympathetic vibration) mentioned previously. If the physical properties of a large mass of tissue or enclosed air are such that it can be set easily into vibrations at a particular rate, then a sound of that frequency in the vicinity will cause the entire mass to vibrate. In this way the feeble sound of finger striking finger is amplified, as illustrated by resonance heard on percussion of the normal thorax or the tympanitic note heard over air-filled viscera.

III

We wish to stress the practical application of these fundamental concepts to the actual procedures by which we elicit and interpret the percussion note and tactile phenomena.

PERCUSSION

The purpose of percussion is to determine the physical properties of tissues by directing sound waves into them and observing the note which results. Since the object is to transmit the percussion blow to the underlying structures, *the pleximeter finger should be pressed very firmly* against the body wall. The plexor finger should strike a *sharp, staccato blow* and be immediately withdrawn to allow the fullest opportunity for vibrations to occur; a laggard blow may damp the vibrations. To offset diffusion (lateral radiation), however, *the percussion blow should be struck perpendicularly* to the surface, so that the resulting note will be affected only by the structures directly beneath. Skoda emphasized that percussion is chiefly *comparative*, and for comparing different areas the *intensity of the blow must be consistent.*

The question of the strength of the blow is somewhat dependent on the individual's reaction. For example, if percussion is performed too forcibly, organs cannot be well outlined because radiating sound waves impinge upon nearby organs or air spaces and confuse the resulting audible tone. This spreading occurs even under the best of conditions, as shown by the difficulty in outlining the right lower border of the heart. On the other hand, to outline masses lying at some depth, a rather heavy blow is required; for instance, the dulness over the left lower lung secondary to cardiac enlargement[4] is best appreciated with a forceful percussion.

It is evident that the percussion note will lie between two broad extremes: a large mass of air may be set into sympathetic vibration and so reinforce the percussion blow, or the sound may be reflected back at once by rigid, nonelastic structures, and only the dull thud of the percussion stroke will be heard. For convenience the sounds elicited are classified into four main gradations between these extremes. These will now be described in terms of their acoustic properties.

1. *Tympany* (Fig. 2, 1.).—Tympany is a definitely musical note, of pure pitch and with few overtones, produced when a mass of air vibrates in sympathy with the percussion note. It is best obtained normally over the region of the cecum or stomach. Whenever heard, it is an indication of the presence of air. Hence in pneumothorax, extreme emphysema, and over large cavities, it is a pathologic sign. Tympany can be approached experimentally by percussion over the normal thorax in full inspiration; such hyperresonance may also be simulated by percussion of a loaf of fresh bread or a feather pillow.

2. *Resonance* (Fig. 2, 2).—Resonance is a note of deeper pitch, richer in overtones and somewhat shorter in duration than tympany. It is the note heard over the normal lung. The elastic tissue of the alveolar walls tends to localize the vibrations and favors the setting up of these overtones by the separate vibration of many different air masses (alveoli).

3. *Dulness* (Figs. 2, 3).—Dulness is higher pitched and of shorter duration than resonance. A dense tissue underlies the pleximeter so that a comparatively small amount of air is set into vibration and the percussion note is only slightly reinforced. Dulness is the normal note over the heart, while over the lung it indicates consolidation, collapse, fluid, fibrosis, congestion, or a thickened pleura or chest wall. *Dulness in place of resonance is always a sign of disease.* "Ubi sonus est altior, ibi est morbus," as Auenbrugger said in 1755.[5]

4. *Flatness.*—Flatness is the epitome of dulness. The pitch is very high; the note is entirely nonmusical, rather a noise than a tone. The duration is minimal; the intensity is minimal; and the pleximeter finger even feels the sense of resistance. There is no reinforcement or sympathetic vibration whatever, and the note heard is simply that of the percussion blow itself. Flatness is the note heard normally over the thigh and pathologically over fluid and very thick tissue.

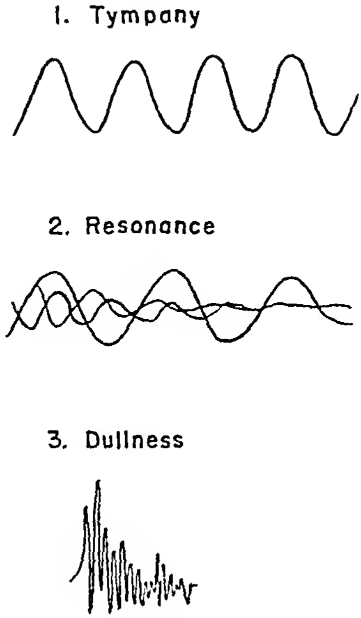

Fig. 2.

TACTILE PHENOMENA

To understand the principles underlying tactile fremitus, we drew the analogy of the human vocal cords, trachea, lungs, and thorax to a wind organ. The vocal cords correspond to the stops; the trachea to the pipe; the lungs to the bellows; the thorax to the resonator. The patient phonates in a full, deep voice, while the examiner's hands are placed on the thorax. Vibrations produced in the larynx pass down the air passages, are reinforced by sympathetically vibrating lungs, and are then transmitted through the pleura and chest wall to the examiner's hands. Fremitus therefore depends upon all the anatomic structures named, their condition, and particularly their physical properties with respect to the passage of sound waves (Fig. 3). Tactile phenomena arising from the movement of the heart, blood, pleural surface, or other viscera will follow the same principles in physics.

1. *Larynx.*—The vibrations of a bass voice correspond closely to the fundamental tone of the normal lung which they set into sympathetic vibration. The higher the pitch of the voice, the weaker are the vibrations one feels. This simple matter of voice quality must always be considered in evaluating fremitus. In weak, high-pitched voices one may feel little or no fremitus. In children, however, the higher-pitched voice corresponds to the fundamental tone of their lung and therefore fremitus is easily felt.

2. *Air Passages.*—The trachea and bronchi must be patent, or the vibrations will not pass freely and fremitus will be diminished or absent as in bronchial obstruction or in collapse of the lung with a closed bronchus. In atelectasis of the lung with an open bronchus the collapsed tissue may rest against the chest wall and so fremitus may be increased.

3. *Lungs.*—In consolidation fremitus is increased, because the solidified lung presents fewer air-tissue interfaces (alveolar septa) at which reflection can occur; and because solidified tissue vibrates more rapidly than does the normal elastic lung, thereby reinforcing the comparatively rapid vibrations of the spoken voice. In emphysema tactile fremitus is decreased because of larger air spaces and inelastic septa, which allow more absorption and diffusion of vibrations before they reach the palpating hand.

4 and 5. *Pleura and Pleural Space.*—These merely transmit the vibrations from lungs to chest wall. Any absorbing or reflecting layer will prevent such transmission; thus in thickened pleura, pleural effusion, and pneumothorax, fremitus is diminished or absent.

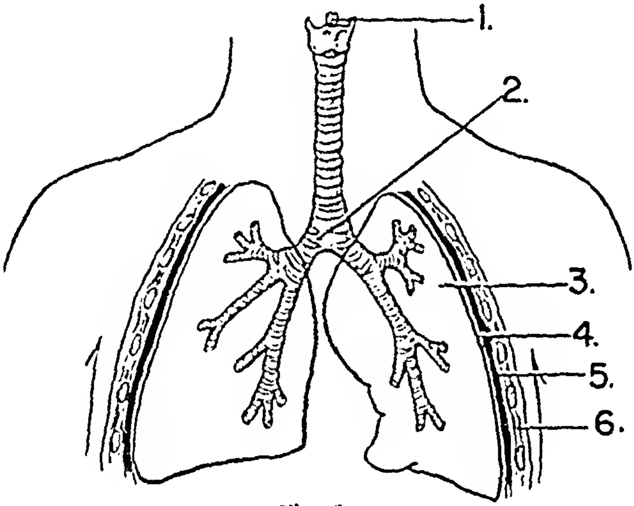

Fig. 3.

6. *Chest Wall.*—Fremitus is decreased over a fat or muscular chest wall because of absorption and diffusion; it is increased over a thin and bony one. One should also remember that for anatomical reasons fremitus is normally greater in certain locations than others. These locations are: (a) Posteriorly, over the right upper lobe, because the trachea lies in direct contact here with the lung apex, while on the left it is separated by the aorta, esophagus, and spongy connective tissue; (b) posteriorly low in the right interscapular area, because the right bronchus which is the direct continuation of the trachea points at this region; (c) in the interspaces rather than over the ribs. It is worth noting that the trachea does not run up and down, but is very oblique, running from the larynx posteriorly to the bifurcation and thence to each lung hilus, very near the posterior boundary of the mediastinum.

CONCLUSION

We offer this review as a guide to the student seeking to acquire skill in the physical examination of the patient. Such skill is not acquired by memo-

rizing lists of diseases and their physical signs, but rather by understanding the physics of sound in relation to normal and diseased tissues.

EFFECT OF TUNGSTEN METAL DIETS IN THE RAT*

F. W. KINARD, PH.D., AND JOHN VAN DE ERVE, M.D., CHARLESTON, S. C.

FEW reports on the toxicity of tungsten metal are recorded in the literature, although the substance has been used as a substitute for bismuth salts in roentgenologic examination of the human gastrointestinal tract.

Bernstein-Kohan[1] killed and examined a rooster three days after he had fed the fowl 438.2 mg. tungsten daily for eight days. No trace of tungsten was found in the kidneys or the liver, but extravasations of blood were found in the mucous membrane of the duodenum, jejunum, and cecum.

Kruger[2] recommended powdered tungsten metal as a substitute for bismuth salts in roentgenologic examination of the gastrointestinal tract. He observed no ill effects in patients given orally 25 to 80 Gm. This followed preliminary work in which 3 rabbits were fed 3 to 5 Gm. of the powdered tungsten metal and 2 dogs were fed 10 to 20 Gm. In no case was there evidence of toxic action.

Waltner[3] incorporated 2 per cent tungsten metal in the McCollum stock diet and fed this to 1- to 2-month-old rats. He stated that growth was somewhat poor, but made no mention of control animals or of the duration of the experiment.

The present work was carried out in order to determine the effects upon the growth of the rat of extended feeding of various levels of powdered tungsten metal. These experiments should give evidence of any marked toxic action of the tungsten.

EXPERIMENTAL

Thirty-eight-day-old animals were chosen from the College colony of mixed Wistar albino and Minnesota piebald rats. Each group was made up of at least 5 females and at least 5 males with the sexes caged separately.

For the experimental diet, powdered tungsten metal† was mixed into the control diet of ground Purina dog chow. Containers of diet remained in the

Received for publication, February 3, 1943.
†General Electric Company, Cleveland Wire Works, Euclid, Ohio.

cages at all times, and a record was kept of the consumption. The rats were weighed at intervals of ten days for a period of seventy days.

At the end of seventy days, the animals were sacrificed and the gastrointestinal tracts were examined grossly.

RESULTS

In Table I, averages for 5 males and for 5 females are listed separately for the control and the three experimental diets. The gain in weight, the diet consumption, and the tungsten (W) consumption, each expressed in grams, are listed for each successive 10-day period. The values for the entire 70-day experimental period are then summed.

TABLE I

DIET CONSUMPTION AND WEIGHT GAINED PER RAT (AVERAGED FOR SUCCESSIVE TEN-DAY PERIODS*)

		CONTROLS		2% W DIET		5% W DIET		10% W DIET	
		MALE	FEMALE	MALE	FEMALE	MALE	FEMALE	MALE	FEMALE
10 days	Gain	38	26	45	41	46	35	47	29
	Diet	120	110	130	110	190	130	140	120
	Tungsten	0.0	0.0	2.6	2.2	9.5	6.5	14.0	12.0
20 days	Gain	36	27	28	22	45	20	37	20
	Diet	110	120	130	100	160	130	150	110
	Tungsten	0.0	0.0	2.6	2.0	8.0	6.5	15.0	11.0
30 days	Gain	40	21	37	15	39	22	41	17
	Diet	140	110	130	100	150	120	150	110
	Tungsten	0.0	0.0	2.6	2.0	7.5	6.0	15.0	11.0
40 days	Gain	24	13	20	12	23	10	27	9

	Diet	140	100	140	110	140	110	150	100
	Tungsten	0.0	0.0	2.8	2.2	7.0	5.5	15.0	10.0
70 days	Gain	9	6	12	5	10	3	11	3
	Diet	130	100	140	110	140	110	140	100
	Tungsten	0.0	0.0	2.8	2.2	7.0	5.5	14.0	10.0
Total	Gain	183	110	172	114	207	107	198	93
Total	Diet	920	770	1050	740	1090	820	1040	750
Total	Tungsten	0.0	0.0	21.0	14.8	54.5	41.0	104.0	75.0

*All values expressed in grams.

No extravasations of blood were evident in the mucous membrane of either the small or large intestine.

DISCUSSION

Over the seventy-day period, the three tungsten diets were without appreciable toxic effect on the males, if growth is used as the criterion. The males upon the 5 per cent and 10 per cent W diets actually showed greater total gains than did the control animals, while the males on the 2 per cent diet gained 6 per cent less than the controls. During the experimental period, each male on the 2 per cent diet consumed an average of 21.0 Gm. of tungsten; on the 5 per cent diet, 54.5 Gm. of W; and on the 10 per cent diet, 104.0 Gm. of W.

The female rats on the 2 per cent and 5 per cent diets showed normal gains despite consumption of 14.8 Gm. and 41.0 Gm. of W, respectively, over the

70-day feeding period. In the females on the 10 per cent diet each consumed a total of 75.0 Gm. of W and gained 15.4 per cent less than the controls. The 75.0 Gm. of tungsten could not be utilized for nutritional purposes, and since these rats consumed even less diet than did the controls, the reduced intake of nutritient material partially, at least, explains the smaller gain. It nevertheless is clear that the 2 per cent, 5 per cent, and 10 per cent W diets did not exhibit marked toxic action.

No extravasation of blood were evident in the mucous membrane of the small or large intestine. This differs from the findings of Bernstein-Kohan, but it is probable that the metal used in the present study was more finely and more uniformly powdered than that used by Bernstein-Kohan and thus mechanical injury was avoided.

It should be pointed out that in this study the growth of the rat is used as the main criterion of toxic action. It is not maintained that the growth study alone will reveal all possible toxic action.

SUMMARY

The feeding of 2 per cent, 5 per cent, and 10 per cent tungsten metal over a period of 70 days is without marked effect upon the growth of the rat, as measured in terms of gain in weight.

Each male of the 10 per cent diet consumed an average of 104.0 Gm. of W during 70 days and maintained normal growth. The females on this diet gained 15.4 per cent less than the controls and consumed 75.0 Gm. of W. This was the greatest variation from normal that was observed.

No extravasations of blood were observed in the gastrointestinal tract.

SULFATHIAZOLE AND STAPHYLOCOCCUS ANTITOXIN IN EXPERIMENTAL STAPHYLOCOCCIC INFECTION*

Edward Steinfield, M.D., Michael Brylawski, M.D.,† and Carrie B. Nash, M.T., Philadelphia, Pa.

BEFORE the advent of chemotherapy with sulfonamide derivatives such as sulfathiazole and sulfadiazine, the literature on staphylococcic bacteremia had concerned itself mainly with forms of serotherapy and the use of bacteriophage. The recognition of exotoxins which were capable of producing many of the toxemic effects of staphylococcic suppuration prompted the use of sera containing adequate amounts of neutralizing substances against these toxins. These antitoxins have been found particularly useful when toxemia rather than bacteremia has been the important source of morbidity. As Spink, Hansen, and Paine[1] have pointed out, there are certain factors which vitiate the efficacy of such sera. These are in brief: (1) The organism may have invasive properties without much exotoxin production; (2) the exotoxin if produced may be neutralized by the serum without checking the inroads of the bacteria; (3) the usual serum though containing antihemolytic factors does not contain antileucocidin substances. We agree in the main with these cogent objections with the reservation that these methods served their purpose in the past. This was particularly so in suppurative processes with toxemia and only intermittent bacteremia. The effectiveness of serum was probably enhanced when other adjuncts were employed, such as bacteriophage, blood transfusion, surgical drainage, and general supportive measures. We have had no experience with Julianelle's rabbit serum, which contains specific carbohydrate precipitins.

The development of specific chemotherapy has changed the whole aspect of this problem, since it has provided the research worker and clinician with radicals capable of bacteriostatic effect even with the disadvantages inherent in all these compounds of lessened penetration into purulent foci. Spink et al.[1] report on the results of chemotherapy with sulfapyridine and sulfathiazole in staphylococcic bacteremia. Six of ten patients treated with sulfapyridine recovered; of nineteen patients treated with sulfathiazole, one died; one other patient died subsequently of myelogenous leucemia. They consider sulfathiazole superior to either sulfanilamide or sulfapyridine and emphasize the necessity of appropriate surgical drainage of abscesses. The use of combined methods of treatment is advocated by Skinner and Keefer,[2] based on a study of 122 cases of staphylococcic bacteremia. They recommend antitoxin, blood transfusion, surgical drainage of foci, and chemotherapy (sulfapyridine or sulfathiazole). They believe that recovery of the host depends on the presence of three conditions: (a) active and viable leucocytes and phagocytes; (b) antibacterial antibodies; and (c) antibodies to the toxins and leucocidin. Brown[4] have reported on experimental chemotherapy and chemoserotherapy in staphylococcic infection. Mice were infected by intravenous injection of broth cultures; in addition, they also inoculated rabbits with broth cultures intravenously once a day for eight days in order to create a septicemic state analogous to clinical infection. Intradermal infection of rabbits was also produced to create spreading lesions due to toxin formation. They concluded that there was a slight but definite increment of therapeutic result with sulfathiazole and serum contrasted with sulfathiazole alone.

We have investigated the use of combined drug and serum therapy of experimental staphylococcic infection in a small but statistically significant group of mice. Sulfadiazine had not yet been described when the experiments were started, and we therefore confined our efforts to sulfathiazole alone and sulfathiazole combined with staphylococcus antitoxin.

TABLE I

CHEMOTHERAPY AND CHEMOSEROTHERAPY OF EXPERIMENTAL STAPHYLOCOCCUS INFECTION

TREATMENT	SINGLE DOSE (DRUG) GM./KG.	DAY OF DEATH
None (control)	—	2 5 2 7 1 8 4 8 1 12 5 12
Sulfathiazole	1.0	5 6 7 18 9 S 12 S 14 S 15 S
Sulfathiazole and serum	1.0 0.5 c.c. of 1:2	4 17 4 18 6 S 10 S 11 S 13 S
Serum	0.5 c.c. of 1:2	3 5 5 6 7 7 17

S = survived.
Ringed numbers are animals showing renal abscesses.

METHODS

Male albino mice were injected intravenously by the dorsal vein of the tail with broth suspensions of a virulent strain of *Staphylococcus aureus*. Approximately 800 million organisms were given in volumes varying from 0.2 to 0.3 c.c. The strain was supplied to us through the kindness of Dr. G. W. Barlow of the Winthrop Chemical Co. and was of proved virulence to mice. We verified its pigment, hemolysin, and coagulase-producing properties. Sulfathiazole in a suspension of acacia was deposited into the stomach transorally with a blunt needle and syringe within 1½, 7, and 24 hours, then once daily thereafter. The dosage of the drug is given in Table I, and the usual bulk of material was 0.4 c.c. The absorption of the drug was proved by levels obtained on sacrificing a number of control mice and pooling the heart's blood. We were able to demonstrate a level of 15 mg. per 100 c.c. in 1½ hours, which, though not so high as figures obtained by van Dyke et al.,[5] were considered fairly adequate. Staphylococcus antitoxin was given in the rear gluteal muscles in doses of 0.5 c.c. of a 1:2 dilution at the same intervals as the drug. This amount corresponded to approximately 166 international units for a 20 Gm. mouse. The antitoxin was used without the drug as a control and also repeated in a small number of animals with the first dose given eighteen hours before infection. The reason for this will be given in the discussion of the results.

After death, animals were examined for abscesses in the kidneys particularly, as well as in other organs; cultures of the heart's blood were taken in those with indefinite or no abscesses and approximately one-half of the others. Survivors were observed for twenty-one days.

RESULTS

In all, 120 mice were used, of which 110 were selected in representative groups satisfactory for statistical purposes. Animals which had died accidentally due to trauma from the peroral injections were discarded.

In the entire group of animals studied, the mean survival time of controls was 6.7 days, whereas in the groups treated with sulfathiazole only and with sulfathiazole and serum, the mean survival times were 13.0 and 12.7 days, respectively. The survival time of animals which received serum only was 6.5 days; this is practically identical with that of the control animals. These figures were subjected to statistical analysis and are recorded in Table II. In a small representative series selected to indicate these factors more clearly, it is noted that one-third of the mice treated with drug only or with drug and serum survived (Table I). Life was definitely prolonged and abscesses noted in only two of those which succumbed. By contrast there were no survivors in the controls or in the serum-treated animals, and abscesses were almost invariably found.

TABLE II

CHEMOTHERAPY AND CHEMOSEROTHERAPY IN EXPERIMENTAL STAPHYLOCOCCUS AUREUS INFECTION: STATISTICAL ANALYSIS OF ENTIRE GROUP

TREATMENT	NO. OF MICE	MEAN SURVIVAL TIME (DAYS)	σ*	STANDARD ERROR OF MEAN
None (control)	30	6.7	2.24	.40
Sulfathiazole	30	13.0	6.7	1.2
Sulfathiazole and serum	30	12.7	6.7	1.2
Serum only	30	6.5	3.82	.84

*σ = Standard Deviation.

DISCUSSION

In common with other observers we found that sulfathiazole prolonged the life of mice infected with *Staphylococcus aureus* and prevented the occurrence of abscesses in the majority of such animals. The properties of this drug (as well as the more recently developed sulfadiazine) are all the more notable, since the massive experimental infection is in direct contrast not only to clinical infection but also to chemotherapeutic experiments upon pneumococci and streptococci. In the latter instance small numbers of virulent bacteria are used, so that quantitative mass relations between the chemical and the bacteria are in favor of the former with resultant sharp readings. The disappointing results with the combination of drug plus serum and with serum only require further elucidation. The potency of the commercial serum is assayed for antihemolytic action, and its dosage is standardized against the international antitoxin unit established by the League of Nations. It contains ample amounts of neutralizing bodies for alpha exotoxin, which is the important toxin in human infections; there is also a fair amount of beta-neutralizing antihemolysin. The latter hemolysin is the hot-cold hemolysin reported by most authors as

incapable of hemolyzing rabbit cells. Roy,[6] however, reports a hot-cold lysin which hemolyzes human as well as rabbit cells despite its resemblance to the beta toxin of Glenny and Stevens.[7] The serum also contains antibacterial bodies which should render it particularly useful in experimental animal infection. Under such conditions bacteremia is a more important issue than toxemia. The time of administration is a factor to be considered, since Farrell and Kitching[8] found that the highest level of absorption in mice did not occur until twelve hours after intraperitoneal injection and eighteen hours after subcutaneous injection. As indicated above, this interval was tested in addition to the method used in the main part of the experiment without materially influencing the results. In addition, such preliminary or prophylactic use of serum bears no resemblance to clinical conditions. We believe that such negative results do not necessarily invalidate the use of sera in clinical infection in which toxemia, longer time element, and reinforcement of natural immunity may tilt the scale in the direction of recovery. A suggestive factor in favor of the serum was noted, though it does not appear in the tables. Occasionally mice treated with drug and serum lived on for several days to a week after cessation of treatment, whereas those treated with drug only succumbed within a day or two after treatment was discontinued. One can speculate that the longer retention of serum created an increment of passive immunity in those mice which were not quickly overwhelmed by the infection.

SUMMARY

1. Sulfathiazole administered perorally prolonged the life of mice infected with *Staphylococcus aureus* and prevented the occurrence of abscesses in the majority of such animals.

2. The mean survival time of animals treated with sulfathiazole was 13.0 days. The mean survival time of those treated with sulfathiazole and staphylococcus antitoxin was 12.7 days. The mean survival time of those treated with serum only was 6.5 days which was practically the same as control animals which received no treatment. The results were further analyzed by statistical methods.

3. Animal experiments with staphylococcic infections do not entirely parallel clinical experience. In the latter certain factors which are discussed indicate that staphylococcic antitoxin may reinforce the immune processes of the host.

CAROTID SINUS SYNDROME: A REPORT OF THREE ADDITIONAL CASES FROM THE CARDIOLOGICAL SERVICE, U. S. V. A. FACILITY, COLUMBIA, SOUTH CAROLINA

S. L. Zimmerman, M.D., Columbia, S. C.

Hering in 1923 conclusively demonstrated that reflex slowing of the heart might be brought about by carotid sinus pressure. Ample confirmation has followed. Particularly elucidative in this respect was the work of Heymans.[1] It was only in recent years, however, that these findings were made applicable to man. Weiss and Baker[2] in 1933 reported fifteen cases of an abnormally sensitive carotid sinus resulting in attacks of syncope and convulsions. Ferris, Capps, and Weiss[3] in 1935 reported an additional thirty-two cases. Since that time numerous similar cases have been reported and now the entity is universally recognized, but, unfortunately, the role it may play in the causation of syncope and unconsciousness is not always borne in mind. The purpose of this paper is to report three additional cases, which were not diagnosed until the patients were hospitalized.

GENERAL CONSIDERATIONS

It is generally recognized that the reflex arc lies within the autonomic nervous system. The afferent pathways lie chiefly in the intercarotid, the glossopharyngeal, and the hypoglossal nerves; in addition, the vagus and cervical sympathetic chains are also involved. Bucy[4] has beautifully recorded the effects of intracranial section of the glossopharyngeal nerve on the blood pressure. In each instance of his four reported cases, a marked rise in blood pressure resulted from such section, and this rise persisted for several days.

The motor pathways are widespread and variable. This factor alone probably contributes largely to the varied clinical responses. Thus in man, the vagus nerve, the vasomotor depressor nerves, and the central motor pathways may be called into play, individually or collectively, and the resultant clinical entity will depend upon the predominance of any particular pathway. Thus, the three types of syndromes recognized have been a vagal type, characterized by cardiac slowing and asystole, followed by syncope and a convulsion; the depressor type, marked by a severe and often alarming fall in blood pressure; and the central type, in which no observable changes in blood pressure or heart rate take place to explain the syncope or convulsion. Commonly, the entity occurs in a mixed form and then it is most usual to classify it according to the most predominant finding. The pure depressor type is probably the least common, Weiss[6] having observed it in pure form in only two cases.

Signs and symptoms other than syncope are not uncommon. Abdominal manifestations are frequently seen, presumably due to a widespread autonomic discharge of the efferent limb of the reflex arc.[5] In order of frequency, fainting, dizziness and weakness, hyperpnea, pallor, bradycardia and asystole, numbing,

Received for publication, February 12, 1943.

Published with the consent of the Medical Director, Veterans' Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the author.

ness and tingling of the extremities, convulsions, drowsiness, epigastric distress, lacrimation, cough, amnesia, and palpitation are listed by Weiss.[6]

Local disease of the carotid sinus has been reported in the majority of cases, and as a group, the incidence of cardiovascular abnormalities was rather high in the reported cases. The average age lies in the fifth decade, but the youngest case reported by Weiss[6] was 13, and the oldest 74. The three reported cases here lie in the fifth decade.

It is a well-known fact that digitalis sensitizes the carotid sinus reflex, and it should be used with caution in elderly patients who complain of spells of weakness or dizziness. A practical point which might be remembered is the danger of its use in combination with anesthesia and manipulation of the neck in the operating room.

Stimulation of the carotid sinus is not wholly without danger. It is not wise to stimulate both at the same time. Marmor and Saperstein[7] reported a case of bilateral thrombosis of anterior cerebral artery following stimulation of a hyperactive carotid sinus, and Galdston[8] et al. reported two cases of thrombosis of the common, internal, and external carotid arteries, associated with hyperactive carotid sinus reflexes of the other side.

The treatment usually starts off as a medical problem, unless the attacks are so frequent and incapacitating that such treatment is not feasible. The general trend is an attempt at correcting all associated abnormalities wherever possible. Constricting collars should be avoided. Emotional upsets, worry, and fatigue should be minimized if at all possible. Reassurance of the patient with reference to epilepsy and organic heart disease is advisable. Specifically, the vagal type often responds to atropine sulfate, $\frac{1}{150}$ grain three to four times daily, orally; this will often prevent spontaneous attacks. Ephedrine, adrenalin, benzedrine, and paredrine may be used in conjunction, in an effort to irritate the ventricle, a state which is conducive to ventricular escape beats upon the occurrence of the usual sinoauricular block. The dose of any of the above drugs should be the minimum necessary to bring about the desired effect.

The depressor type may often be relieved with any of the sympathomimetic drugs, the longer acting ones being the more desirable. Ephedrine sulfate in doses of $\frac{3}{8}$ grain, three to four times daily, has been satisfactory. Benzedrine is probably longer acting and tolerated better by some. The dose ranges between 10 to 20 mg. three times daily. It is said that the side effects are less.

The cerebral type offers a more difficult problem. Here, prime attention must be paid to the associated pathologic condition. Any deficiencies must be treated along generally acceptable lines. Often surgical denervation offers the best hope in these cases. In any case, however, surgery may have to be resorted to if the medical therapy fails. The results have been good as a whole. Recurrences have been few, and an interesting point in this respect has been brought out by Weiss[6]; namely, that those patients in whom a severe, widespread neurosis, associated with a low basal metabolic rate is present, fare poorly, and such condition is considered by him a contraindication to surgical intervention.

CASE REPORTS

CASE 1.—Mr. T. A. B., Reg. No. 28266, a 58-year-old white male, civil engineer by occupation, was admitted for the first time to the United States Veterans' Administration

Facility at Columbia, South Carolina, February 26, 1942, with an admitting diagnosis of "seizures, type undetermined." The family history was irrelevant. There was no history of epilepsy or other neuropsychiatric disorders in the family. Mother died at the age of 70 from "old age" and pneumonia. Father died at the age of 85. One brother died at the age of 35 of pneumonia.

The past history included the usual childhood diseases. He had typhoid fever at the age of 15, influenza in 1918, was hospitalized in 1932 for "arthritis." Venereal disease was denied.

He was seen by me February 27, 1942, after he had been referred for cardiac consultation by the neuropsychiatric service. The history obtained was as follows: There was no history suggestive of a diminished cardiac reserve, the patient denying exertional dyspnea, dependent edema, paroxysmal nocturnal dyspnea, and precordial or retrosternal pain related to exertion. He was not a known hypertensive. The first attack of syncope occurred in December, 1941, at which time he attempted to switch off the radio while in bed. This necessitated a movement of his head to the right, and it was followed immediately by an unconscious state, during which, his wife stated, both hands were drawn upward toward the shoulders. There was no convulsion, nor was there any incontinence, and he did not bite his tongue. The next attack occurred at 10:30 A.M., February 26, 1942, while attempting to put his right arm in the torn sleeve of his overcoat. That was all he remembered. He was observed to have fallen to the ground, injuring his face and left elbow. The right side of his tongue was cut.

Physical examination at the time of admission revealed a well-developed, well-nourished white male, weighing 158 pounds, 73 inches tall. There were bruises and abrasions of his face and elbow. The lungs were negative. Blood pressure was 128/80, the rhythm regular, and no cardiac enlargement was noted. There were no thrills or murmurs. Arcus senilis was present, and there was peripheral arteriosclerosis. Because of the suggestive history, a carotid sinus syndrome was suspected by the cardiologist, and, on February 27, 1942, a preliminary examination revealed the pulse to be 72, blood pressure 128/80, and the rhythm regular. While in the sitting position, stimulation of the right carotid sinus made the patient dizzy, and he keeled over. The blood pressure fell to 98/60. With this syndrome as the probable diagnosis, other possible etiological factors were investigated by the cardiological service.

The retinal vessels were within normal limits and there was no evidence of increased intracranial pressure. The discs were clear. The electrocardiogram revealed a regular sinus rhythm and a rate of 75. All QRS complexes were upright. The T waves were normal, and there was no significant ST deviation. The conduction was normal throughout. The interpretation was "within normal limits." X-ray of the skull revealed no abnormalities. X-ray of the chest revealed a thickening of the pleura and some coarse peribronchial thickening in the mid-portion and bases of both lung fields. The aortic, cardiac, and diaphragmatic shadows were normal. The red blood count was recorded as 3.69 million with 67.5 per cent hemoglobin on February 23, 1942, and 5.04 million with 73 per cent hemoglobin on March 3, 1942. The smear was not remarkable. The white blood count was reported within normal limits. The sedimentation index was 23 mm. per hour (Westergren). The urine revealed a specific gravity of 1.020 and was entirely normal. The Wassermann and Kahn tests were negative. Spinal tap was performed March 4, 1942. The fluid was clear, the pressure normal. The globulin test was negative; there were 2 cells per c.mm.; the dextrose was normal and the Wassermann reaction was negative. The Lange colloidal gold test was negative. Three basal metabolic rates were obtained, with readings of minus 13 per cent, minus 21 per cent, and minus 25 per cent reported.

On March 2, 1942, the syndrome was again tested. Pressure on the right carotid sinus resulted in syncope. The right side of the face was pulled upward and the patient lost all contact with his surroundings and fell over to the left. The blood pressure fell from 110/80 to zero? The rhythm remained regular and did not slow.

On March 3, he was presented to the Clinical Pathological Conference, Dr. J. Heyward Gibbes of Columbia, presiding. Following stimulation of the right carotid sinus, the blood pressure fell from a level of 140/90 to 50/30, and the patient "passed out" completely. There was no change in pulse rate or rhythm. When stimulation was stopped, the

patient remained confused for a few moments and then returned to his normal state. Again the face was drawn upward on the right and he fell to the left. Pressure on the left carotid sinus failed to result in any abnormal reaction. He was placed on ephedrine sulfate, ¾ grain, twice a day, and given one grain of thyroid daily, receiving no other medication. He had no further spontaneous attacks while hospitalized. Subsequent attempts at causing syncope failed entirely. The patient gained nine pounds in weight and was discharged March 23, 1942, with instructions to continue the intake of ephedrine sulfate. The final diagnoses were:

1. Carotid Sinus Syndrome, Right, with Syncope, Depressor Type.
2. Arteriosclerosis, Radial and Brachial Vessels.

Follow-up: He again reported to me and stated that he suffered with a few more similar attacks, but admitted that he had not continued the ephedrine.

CASE 2.—Mr. W. L. S., Reg. No. 29612, a 46-year-old white male, was admitted for the first time to the United States Veterans' Administration at Columbia, S. C., on July 13th for the treatment of an upper respiratory infection. The family history was noncontributory, except that one sister had died at the age of 44 of Bright's Disease. He had the "usual" childhood diseases, and the remainder of the past history was irrelevant. Syphilis was denied. He used no drugs, nor did he use excessive amounts of alcohol.

The history revealed that the patient contracted an upper respiratory infection resulting in hoarseness and cough which began three weeks prior to admission. During these paroxysms of cough he became unconscious, having had nine such attacks in the preceding three weeks. Two such attacks occurred during the first two weeks of admission.

Routine admission examination revealed a blood pressure of 146/76 and some arteriosclerosis of the radial vessels. A special eye, ear, nose, and throat examination by the consultant revealed an acute catarrhal pharyngitis and laryngitis. He was seen by the neuropsychiatrist, who found nothing of relevance.

Blood and urinary work-up were not remarkable. The Wassermann and Kahn tests were negative. Spinal fluid was normal and the pressure was not increased. X-ray of the skull revealed three unexplained areas of rarefaction in the frontal region. X-ray of the chest was negative. Electrocardiogram revealed left axis deviation, some slurring of the QRS complexes and low T waves in all leads. No conduction defect was noted. The rhythm was normal sinus.

He was seen in consultation by the Cardiological Service, at which time the following was noted: He had enjoyed good health and had no diseases of relevance until eight weeks prior to admission, at which time he "caught a cold" and suffered severe paroxysms of coughing. A tentative diagnosis of whooping cough was made by his local physician. He was not a known hypertensive, was never a congestive failure, and there was no history of coronary insufficiency. The first attack of syncope followed a coughing paroxysm and occurred while the patient was in a sitting position. He lost consciousness (he was told this) for a few minutes. There was no generalized convulsion, no loss of sphincteric control, and he did not bite his tongue. He aroused in a few moments. Eight or nine similar attacks followed, and each was brought on by a short coughing paroxysm. No voluntary movement of the head or neck could precipitate an attack.

The relevant findings in the cardiovascular examination revealed a normal-sized heart with a soft systolic blow over the aortic area. A-2 and P-2 were approximately equal. The pulse was 72 and the blood pressure 110/70 in the sitting position. The radial and brachial vessels were soft and compressible. Visualization of the fundi revealed mild tortuosity of the vessels. There was no evidence of failure.

On August 11, 1942, stimulation of the right carotid sinus caused a typical syncopal attack. There was a complete asystole; no heart sounds at all were heard, and the blood pressure fell to zero. With this definite clue, the entire procedure was repeated and a simultaneous first-lead electrocardiogram was obtained. With the patient in a sitting position, stimulation of the left carotid sinus for about thirty seconds caused the patient to lose consciousness. The eyeballs rolled upward and he fell over to the left side. Recovery was rapid following cessation of stimulation. Complete asystole followed a slowing of the heart rate (Fig. 1).

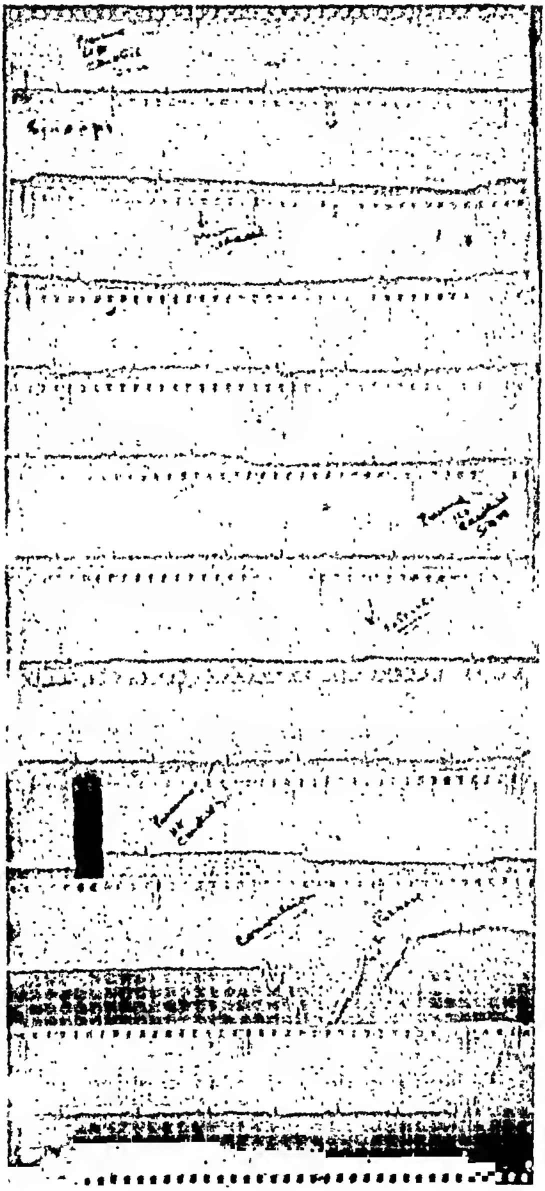

Fig. 1.—Patient W. S. Continuous tracing, Lead I, showing the effect of carotid sinus pressure. At the top of this tracing three complexes are noted, and at the indicated point, pressure was applied on the left carotid sinus. Patient fainted, and the pressure was not applied steadily and constantly. Note that following the asystole there are four contractions recorded, originating in the S-A node. At the arrow the pressure was released and cardiac activity was resumed. At first it was slow and later at a more rapid rate. Pressure on the right carotid sinus was applied, as indicated, and again there is a long pause, followed by an occasional contraction. Pressure was released at the point indicated and then reapplied on the right carotid sinus. This was followed by a complete asystole and syncope and finally a convulsion, at which point the pressure was again released. It is noted that there are no nodal or ventricular escapes.

A short while later the right carotid sinus was stimulated, and pressure for about thirty to forty seconds resulted in loss of consciousness and a short clonic convulsion, which lasted as long as stimulation was continued and ceased soon after the cessation of stimulation of the right carotid sinus. The blood pressure fell, secondarily to the asystole.

The diagnosis was: carotid sinus syndrome, bilateral, with syncope, of the vagal type.

The patient was placed on atropine sulfate, 1/150 grain three times a day, and was discharged soon thereafter, having been advised to continue this medication. He has not been heard of since his discharge on September 19, 1942. Whether or not the upper respiratory infection was the sensitizing factor and the cough the trigger mechanism is unknown. Certainly it appears likely that such was the case.

CASE 3.—Mr. L. S., Reg. No. 29796, a 52-year-old white male, was admitted for the first time to the United States Veterans' Hospital, Columbia, S. C., July 29, 1942, complaining of fainting spells of three years' duration. The family history was noncontributory. He had the "usual childhood diseases," typhoid fever in 1912, and denied any venereal infection.

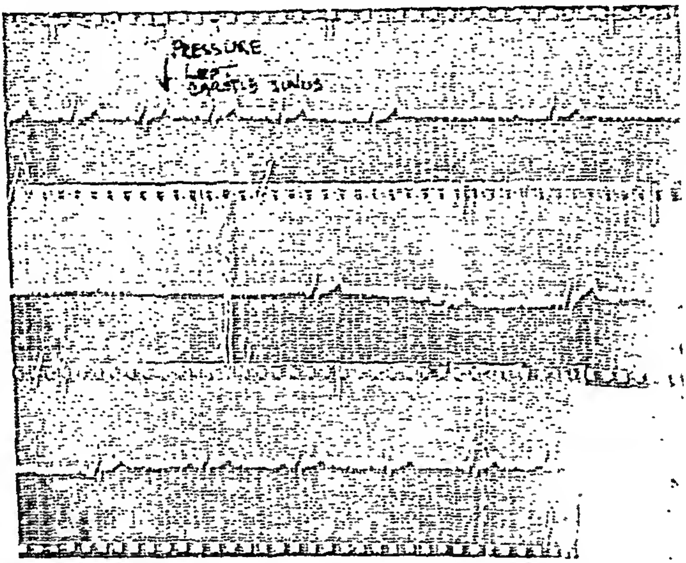

Fig. 2.—Patient L. S. Pressure on left carotid sinus, at the indicated point, resulted in, first, a slowing of the normal sinus rhythm, and then a complete asystole, followed by syncope. The point of release of pressure is not indicated on this tracing, but it is noted that upon cessation of asystole the normal sinus rhythm reappeared, at first slow, and then at a more rapid rate.

The history given to the admitting office revealed that he had "spells," consisting of "shaking and swishing noises in his head," complete blindness, and falling to the ground, for three years prior to admission. He stated that exertion brought on these attacks. Consciousness was regained soon after falling to the ground. He also complained of weakness, stating that he lost 30 pounds during the two months prior to admission. He stated that once the shaking had started, he could prevent the rest of the spell by holding his head still between both hands. The remaining history was irrelevant.

Examination at the time of admission revealed a blood pressure of 120/80. The heart tones were recorded as faint, but there was no enlargement, no murmurs, nor arrhythmia. The remainder of the examination was negative, including a neurological examination.

The blood, urinary work-up, including modified Mosenthal, phenolsulfonphthalein output, nonprotein nitrogen determination, and microscopic urine examinations, were within normal limits. The Wassermann and Kahn tests were negative. Spinal fluid was crystal clear, under normal pressure, and negative in all other respects. The colloidal gold test was negative. X-ray of the skull, lumbosacral spine, and hips was normal. X-ray of the chest was negative. Four-lead electrocardiogram was within normal limits.

He was seen in consultation by the Cardiological Service on August 18, 1942, at which time further history revealed that these attacks could be brought on by unusual movements of the head. The frequency varied, sometimes occurring as often as two or three times per week, but usually not so often. There was no history of bladder or rectal incontinence; he never bit his tongue; and he was never told that he had a generalized convulsion during any of these attacks. At times he said he felt as though a fly were in his left ear. No history was obtained of coronary insufficiency nor of pre-existing hypertension.

Cardiac examination revealed no increase in heart size, regular sinus rhythm, and no thrills or murmurs. The first apical sound was recorded as "poor." A-2 and P-2 were equal. There was no peripheral sclerosis and no evidence of congestive failure. The retinal vessels were normal.

Pressure on the right carotid sinus did not slow the heart rate nor reduce the blood pressure, and resulted in no clinical manifestation of syncope. Very little pressure on the left carotid sinus, of short duration, resulted in complete asystole, followed by syncope. (See Fig. 2.)

A clinical diagnosis of carotid sinus syndrome, left, of the vagal type, with syncope, was made. He was placed on atropine sulfate, by mouth, in doses of $\frac{1}{150}$ grain, for a period of three weeks, had no recurrence, and was discharged on September 2, 1942. He has not been heard from since.

SUMMARY

1. Three cases of carotid sinus syndrome, two of the vagal type and one of the depressor type, are reported. In all, medical treatment afforded some relief. One of the patients with the depressor type had an associated low basal metabolic rate. His response to medication was not reliable, possibly in view of his failure to diligently take the ephedrine. The results with the vagal type cases have been more encouraging.

2. In all three of these reported cases the presence of the syndrome was easily established. In two the history revealed the precipitating factor, to be an abnormal or sudden movement of the head and neck. In the third, the patient learned that he could avoid such an attack by holding his head still between his hands.

3. The syndrome should be borne in mind in all cases of unexplained syncope, especially if associated with abnormal movements of the head and neck.

ADDENDUM

Since the above paper was submitted for publication, three more cases of carotid sinus syndrome of the vagal type were observed.

CASE 1.—The first was noted in a 60-year-old Negro male, a railroad worker by occupation, who had an attack of unconsciousness of unknown cause about six years ago, followed by numerous attacks of giddiness and "swimming sensation in his head." No further attacks of outright syncope occurred and on the outside he was diagnosed as having coronary disease. When seen, he presented marked hypersensitivity of the right carotid sinus, resulting in asystole and syncope. He was a known hypertensive, and electrocardiogram revealed evidences of myocardial disease. Because of the fact he was not admitted for treatment, further observation was impossible.

CASE 2.—The second case noted was in a 53-year-old white male, a textile worker by occupation, who was admitted because of bilateral deafness of the perception type, with degeneration of the right auditory nerve. He had no spontaneous attacks of syncope, and, when routinely examined on the cardiac service, he presented a very definite bilateral carotid sinus syndrome of the vagal type, with asystole and syncope. At present, he is being treated with atropine sulfate, grain $\frac{1}{150}$, orally, three times daily. He has not been observed sufficiently to determine whether or not this will be effective. Aside from some arteriosclerosis of the peripheral and retinal vessels, cardiological work-up was essentially normal. He returned subsequently, having had three spontaneous attacks of syncope. His response to atropine was poor, and he will in all probability come to surgery.

CASE 3.—A 72-year-old white male, a known hypertensive and coronary arteriosclerotic cardiac patient, entered with a history revealing three recent spontaneous syncopal attacks of unknown etiology. The case proved to be one of extremely sensitive left carotid sinus syndrome of the vagal type with asystole and syncope. Atropine and ephedrine, in large doses, have prevented further spontaneous attacks.

THE INFLUENCE OF MUSCULAR WORK AND FATIGUE ON THE STATE OF THE CENTRAL NERVOUS SYSTEM*

ERNST SIMONSON, M.D., NORBERT ENZER, M.D., AND ROY W. BENTON, M.D., MILWAUKEE, WIS.

INTRODUCTION

THE reciprocal relationship between muscular fatigue and fatigue of the central nervous system has theoretical interest and practical application. Most industrial occupations involve muscular work as well as functions of the central nervous system. Hence, the development of general fatigue in industry depends on the influence of both systems on one another. It would seem that knowledge of this relationship could be useful in military affairs, since there are many occupations and situations in which fatigue of the central nervous system contributes to general fatigue arising out of muscular strain or effort. Concerning this question, no experimental material is available, so that Ivy[1] in a recent review states only, "As is well known, heavy muscular exercise influences mental performance because of the tendency to fall asleep." It would be practical to know what amount of muscular work is necessary to produce a depressing effect on the central nervous system, how long the effect lasts, and whether the type of work is an influencing factor. From a theore-

Received for publication, February 12, 1943.

tical point of view it would be interesting to investigate the mechanism of the depressing effect. While the depression of the central nervous system by muscular fatigue has been generally accepted as a fact on the basis of subjective experience, little is known of the effects of short, moderate muscular work on the state of the central nervous system; i.e., whether short, moderate muscular work exerts a stimulating effect. The fusion frequency of flicker seems to be a method suitable for the study of the influence of muscular work on the state of the central nervous system. The fusion frequency of flicker is that rate of successive light stimuli necessary to produce an effect equal to continuous illumination. It depends on chronaxie, latent period, and refractory period of the visual system (retina, visual pathways, visual centers); therefore, it indicates the excitability of the visual system, and perhaps, to a certain degree, the excitability of the whole central nervous system. It has been repeatedly demonstrated that general fatigue develops first in the sensory centers.[2] The fusion frequency of flicker is depressed in fatigue of the central nervous system,[3, 4] in pathologic fatigue of patients with hypothyroidism,[5] or circulatory insufficiency;[6] on the other hand, the fusion frequency of flicker increased parallel to the relief of fatigue in patients with hypogonadism after treatment with testosterone,[7] and in normal subjects after benzedrine[8] and pervitin.[9] The fusion frequency of flicker can be measured with great accuracy, and cannot be influenced by effort or by training. The effect of muscular work on the central nervous system probably depends on the physical condition and sensitivity or resistance of the central nervous system of the individual subject. Therefore, equal effects of a given standard type of work cannot be expected to result in different people. Short, moderate exercise might produce a depression of the excitability of the central nervous system in a weak subject, while a rather strenuous muscular effort might fail to do so in a stronger subject. Hence, it would seem to be more proper to express the results of this study in terms of distribution of deviations in a group of 54 subjects. Each type of work might increase the excitability of the central nervous system in some subjects and depress it in others. But a shift from prevailing stimulating effects in the majority of subjects after short, moderate exercise to prevailing depressing effects after more strenuous exercise may be expected. Four different types of work were investigated:

1. Static work, where fatigue is rather localized.
2. Short, moderate exercise (30 genuflexions), without fatigue.
3. Pulley, for three minutes or until fatigue.
4. Running until fatigue.

Although the performance of these different types of work cannot be compared on a quantitative basis, it is clear that the effort increases from Type 1 to Type 4.

METHOD

The fusion frequency of flicker was measured under standard conditions of surrounding illumination, illumination of the test patch, visual angle, light-dark ratio, and exposure. Direct current was used for the light source. Details of method and procedure are described in an earlier publication.[3] The

fusion frequency of flicker was measured before the exercise and ½, 1, 2, 3, etc., minutes after the exercise. The fusion frequency was also measured during the static exercise, where the subject remained in the same sitting position as used for the determination of the fusion frequency. In the other types of exercise, it was not possible to do so.

Types of work.—(a) Static exercise: The subject had to hold a load of 8 pounds with the right arm straight in horizontal position until completely fatigued.

(b) 30 genuflexions were performed within one minute according to the rhythm of a metronome. This exercise did not produce fatigue, so that the subjects would have been able to continue.

(c) Horizontal pull with both arms of a pulley weight of 26 pounds at a rate of 20 per minute for women and 30 per minute for men. The stop signal was given after three minutes, but 16 subjects ceased work earlier because of fatigue.

(d) Running: The subjects were asked to run through a corridor of 33.5 meters' length back and forth until fatigued. Although they were urged to run fast, there were great individual variations of speed (between 1.43 and 4.19 meters per second), total distance (from 201 and 737 meters), and time (from 70 to 300 seconds). There was no inverse ratio between speed and duration, so that the individual differences must be explained by different physical and training condition, and perhaps by different willingness to exhaust themselves. If the subject did not break off the exercise earlier, the stop signal was given after 670 meters (Nos. 6. 17, 19, 20, 29, 33, 39, and 44), in one subject (No. 8) after 737 meters, in order to avoid too great differences in the amount of work performed. One subject (No. 16) broke off the performance after 80 seconds because of side pains, which occurred also in a second investigation after several weeks' interval. Although the running exercise cannot be regarded as standardized, it was for each subject by far the hardest exercise test, compared to the other tests, "a", "b", and "c". Only one exercise test was investigated at a time, so that there was an interval of several weeks between the different exercise tests for each subject. The investigations were performed at the same time (1½ hours after lunch). All results are given as deviation from the initial value before the exercise.

SUBJECTS

The 54 normal subjects (25 men. 29 women) ranged from 18 to 38 years. The average age of the male subjects was 33.3 years, that of the female subjects was 27.4 years. All passed through a medical examination, and none showed any abnormal findings. The height of the group of male subjects varied from 5 feet, 1⅞ inches to 6 feet. 1¾ inches, the weight from 130 to 207½ pounds. The correspondent values for the group of women are: Height 5 feet, 2 inches to 5 feet 9½ inches, and weight from 111 to 141½ pounds. They were employed in sedentary occupations. Only a few (4 men, 1 woman) were in a training condition which could be considered as above the average, i.e., they were participating rather regularly in athletic games or exercises; the others did so only occasionally, at greater intervals, or not at all. In this respect the

TABLE I

EFFECT OF FOUR TYPES OF MUSCULAR WORK ON THE FUSION FREQUENCY OF FLICKER, EXPRESSED IN NUMBER AND PERCENTAGE OF DEVIATIONS RELATED TO THE TOTAL NUMBER OF CASES

1 TYPE OF WORK	2 TOTAL NO. OF CASES	3 ONLY INCREASE	4 INCREASE AND DECREASE	5 ONLY DECREASE	6 ALL INCREASES	7 ALL DECREASES	8 WITHOUT CHANGE
(a) Static Exercise	53	42 = 79.2%	7 = 13.2%	3 = 5.6%	49 = 92.5%	10 = 18.8%	1 = 1.9%
(b) Genuflexions I	54	34 = 63.0%	12 = 22.2%	6 = 11.1%	46 = 85.2%	18 = 33.3%	2 = 3.7%
Genuflexions II	47	31 = 66.0%	10 = 21.3%	5 = 10.6%	41 = 87.3%	15 = 31.9%	1 = 2.1%
(c) Pulley	49	20 = 40.8%	18 = 36.7%	10 = 20.4%	38 = 77.5%	28 = 57.2%	1 = 2.0%
(d) Running	52	2 = 3.8%	11 = 21.2%	39 = 75.0%	13 = 25.0%	50 = 96.2%	

experimental group may be regarded as a fairly good average of normal population.

During the period of investigations several subjects dropped out, so that the total number of subjects was 53 for the static exercise, 52 for the running exercise, and 49 for the pulley exercise. At the end, test "b" (genuflexions) was repeated on 47 subjects. Thus, the experimental material covers about 2,500 determinations of the fusion frequency.

RESULTS

Table I shows the effect of the four types of muscular work on the fusion frequency of flicker, expressed as frequency of positive (stimulation) and negative (depression) deviations, absolute as well as in percentage of the total number of cases (column 2). Column 3 shows the number of cases who responded to exercise with only an increase, column 5 those who responded only with decrease, while column 4 shows the cases where increase as well as decrease were observed during the recovery period. Column 6 shows all cases with increase, i.e., the sum of columns 3 and 4, while column 7 shows all cases with depression, i.e., the sum of columns 4 and 5. Only in five experiments, muscular exercise (genuflexions, pulley exercise) failed to produce a definite response; in all other experiments the deviations exceeded the experimental error. Table I shows that any type of exercise may produce an increase of the fusion frequency of flicker in some subjects and a depression in others, but there was a pronounced shift of their distribution. The number of cases who responded only with increase (column 3) decreased from 79.2 per cent in static exercise to 63.0 and 66.0 per cent in genuflexions, to 40.8 per cent in the pulley exercise, and to 3.8 per cent in the hardest type of exercise (running). Accordingly, the number of cases who responded only with depression (column 5) was lowest in the static exercise (5.6 per cent) and highest after running (75 per cent). The same inverse relationship can also be seen in columns 6 and 7. While increase after static exercise and genuflexions occurs in 85 to 90 per cent of all cases, a depression is observed in 96.0 per cent after running. These results show that muscular exercise may increase as well as depress the excitability of the central nervous system; the factors responsible for the stimulating effect prevail in short, moderate exercise, while the depressing factors prevail in hard exercise. In intermediate types of exercise, such as the pulley exercise, 36.7 per cent show increase as well as decrease. The error of the percentage of increases (column 6) and decreases (column 7) was calculated according to the formula $\pm\sqrt{\frac{P_1\% \cdot P_2\%}{n}}$ where P_2 per cent $= 100 - P_1$ per cent (Poll[11]).

For the static exercise, the error of the percentage of all increases was ±3.618; that of the percentage of all decreases was ±5.367. The corresponding values for Genuflexions I were ±4.832 and ±6.404, respectively; for Genuflexions II, ±4.873 and ±6.783, respectively; for the pulley exercise, ±5.965 and ±7.069, respectively; for the running exercise, ±6.005 and ±2.699, respectively. The limit of statistical reliability is regarded to be three times these values. This means that the prevailing increase of the fusion frequency after static exercise

TABLE II

LIMITS, AVERAGE, AND DISTRIBUTION OF MAXIMUM DEVIATIONS OF THE FUSION FREQUENCY OF FLICKER, IN PERCENTAGE OF THE TOTAL NUMBER OF OBSERVATIONS, AFTER FOUR TYPES OF MUSCULAR PERFORMANCE

TYPE OF WORK	1	2	3	DISTRIBUTION 4											
	MAX. DECR.	MAX. INCR.	AVER.	-10 TO -8.1	-8 TO -6.1	-6 TO -4.1	-4 TO -2.1	-2 TO -0.1	+2 TO +0.1	+4 TO +2.1	+6 TO +4.1	+8 TO +6.1	+10 TO +8.1	+12 TO +10.1	OVER +12.1
(a) Static Exercise	-4.4	+13.2	+3.84			3.4	6.8	6.8	13.5	28.9	25.4	8.5		5.1	1.7
(b) Genuflexions I	-5.6	+14.0	+2.46			3.1	14.1	10.9	12.5	28.1	18.8	9.4	1.6		1.6
Genuflexions II	-5.8	+13.2	+2.97			3.6	10.9	12.7	14.5	36.4	7.3	5.5	5.5		3.6
(c) Pulley	-8.8	+20.8	+0.97	1.5	1.5	7.5	19.4	13.4	17.9	23.9	5.9	5.9	1.5		1.5
(d) Running	-9.6	+ 8.0	-3.77	3.2	14.5	30.6	24.6	6.4	6.4	6.4	6.4	1.6			

and genuflexions and the prevailing decrease after running are statistically significant. On the other hand, the prevailing of the percentage of increases after the pulley exercise is only a tendency without statistical significance. Significant are also the high percentage of increases in types "a" and "b," compared to the low percentage in type "d"; and the high percentage of decreases in type "d," compared to the lower percentage in types "a" and "b." It is interesting that the amount of work producing a depression of the fusion frequency is rather small; in three subjects the speed of running was slow (subjects 1, 12, and 49), or the distance was small (subjects 3, 12, 21, 22, and 49); nevertheless, a distinct depression was observed. Only a rather short, moderate type of work produces increase of fusion frequency in the majority of *normal* subjects. There was no direct relationship between the frequency or the magnitude of the increase in types "a" and "b" and the training condition. For instance, genuflexions failed to produce any distinct deviation in one of the best trained subjects (No. 8). It is possible that the "moderate" type of exercise was too slight for this subject to provoke any response of the central nervous system.

Table II shows the magnitude of the deviation of fusion frequency after muscular work. Only the maximum deviation is considered. Column 1 shows the maximum depression of the whole group; column 2 shows the maximum increase. The lowest depression is –4.4 after static exercise and increases to –9.6 after running. Occasionally also, moderate types of work may produce marked depression. The upper limit of increase (column 2) is smallest after running (+8.0). The distribution (4) is given in intervals of deviation from –10 to –8.1, from –8.0 to –6.1, etc., as percentage of the total number of observations. The distribution of the values in intervals of distinct, but not extreme, responses, such as –4 and –6, and +4, reflect the tendency much better than the stray values of extreme limits (columns 1 and 2). The percentage of observed depressions in the intervals –4 and –6 increases from type "a" to type "d," so that for type "d" depressions ranging between –2.1 and –4.0 are about four times as frequent as for type "a," and this is even more manifest for the interval between –4.1 to –6.0 deviation. Type "b" (genuflexions) was repeated after an interval of three months. For the second investigation only 47 subjects were available. The limits, averages, and distribution of increase and depression are similar in the first (Genuflexions I) and second (Genuflexions II) investigation. This shows that the distribution of values is rather constant and characterstic for the given type of exercise.

Table III shows the duration of deviations of the *fusion* frequency, subdivided into two groups with durations of less or more than eight minutes. The time of eight minutes is arbitrary. The duration of the increase exceeds eight minutes in ten to fourteen cases in types "b" and "c," while five cases after static exercise and only one case after running show a duration of increase exceeding eight minutes. The lower incidence of longer lasting increases after static exercise may be explained by the comparatively small amount of work performed in this type of exercise. Also, the duration of decrease is less than eight minutes in all cases after static exercise, and in 28 of 31 observations after Genuflexions I and II. There are almost as many cases with depressions ex-

ceeding eight minutes as those less than eight minutes after pulley exercise, while the depression lasts longer than eight minutes in the majority of cases after running. In several cases, the values were still distinctly depressed sixteen and nineteen minutes after the exercise. A short, hard exercise may depress the excitability of the central nervous system for a rather prolonged time.

No relationship was found between speed, time, and distance in running and the magnitude of deviations. The deviations apparently depend at least as much on individual constitutional factors as on the amount of work performed.

TABLE III

DURATION OF DEVIATIONS OF FUSION FREQUENCY OF FLICKER AFTER MUSCULAR WORK

TYPE OF WORK	DURATION OF INCREASE: LESS THAN EIGHT MINUTES	DURATION OF INCREASE: MORE THAN EIGHT MINUTES	DURATION OF DECREASE: LESS THAN EIGHT MINUTES	DURATION OF DECREASE: MORE THAN EIGHT MINUTES
(a) Static Exercise	43	5	9	–
(b) Genuflexions I	35	11	16	2
Genuflexions II	27	14	12	1
(c) Pulley	28	10	15	13
(d) Running	11	1	15	35

Fig. 1 shows two typical responses for each type of exercise: The short, but pronounced, increase during and after static exercise, the prolonged depression after running, and the wavelike reaction after pulley exercise. The response after running is also wavelike; however, with the level below the resting value, while the waves oscillate around the resting value after pulley exercise. Wavelike reactions also were observed on an elevated level after genuflexions, although less frequent.* It appears that stimulating as well as depressing factors are present during the whole period of recovery after exercise, reaching their maximum at different times.

Our material (25 men, 29 women) allows the comparison of performance as well as of response of the fusion frequency between men and women. The comparison of performance between men and women has some interest because the material on this question is scanty. A difference of the average between the group of men and the group of women was regarded to be significant when exceeding the value of $2\sqrt{SE_1^2 + SE_2^2}$. The average duration of static performance in 25 men was 53 seconds, that of 28 women only 27 seconds. The difference (26 seconds) was highly significant, the value of the expression being only 6.672.

The pulley exercise was stopped after three minutes, so that no statistical comparison of endurance is possible. The male subjects worked at a rate of 30 per minute, the women at the rate of 20 per minute, so that the performance of women was only ⅔ that of men. There is some evidence, however, that the endurance of women was inferior also in this type of work. Out of 25 men, only three stopped working before three minutes because of fatigue, while 13 out of 24 women did so, although they worked at a slower rate.

In regard to running exercise, the performance of women was inferior in all respects (distance, speed, duration). The subjects were instructed to run

*Allen and Schwartz[10] observed wavelike responses of the fusion frequency of flicker after stimulation of the sense of taste, smell, and after acoustical stimulation.

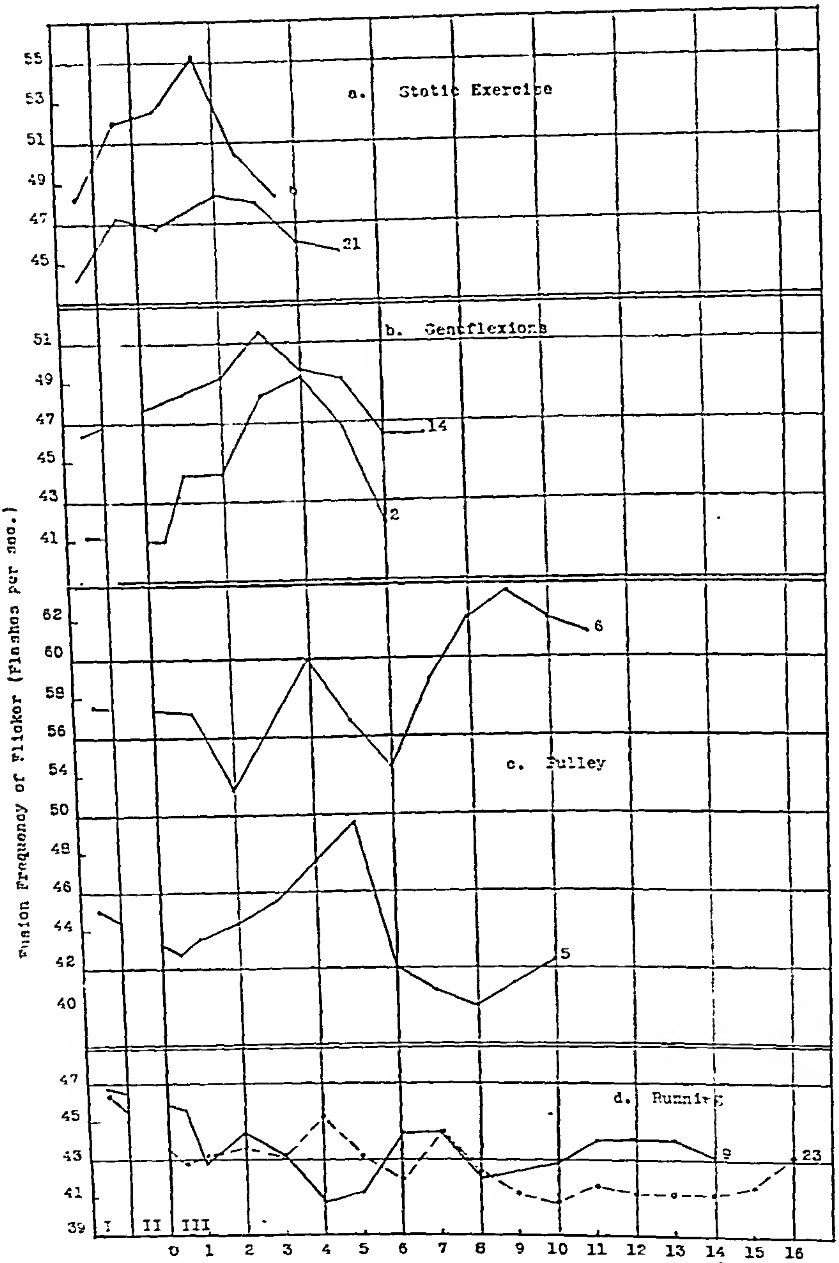

Fig. 1.—Typical effect of four types of muscular work with increasing effort (*a*, static exercise; *b*, genuflexions; *c*, pulley exercise; *d*, running) on the fusion frequency of flicker (flashes per second). "I" means the initial fusion frequency before the exercise; "II" means the period of exercise; during this period the fusion frequency was measured only in type a; "III" means the recovery period after the exercise. The subjects, from whom the curves are taken, are indicated by their numbers. The typical response after short, moderate exercise (types a and b) is an increase of the fusion frequency, while hard exercise (type d) produces prolonged depression. The fusion frequency is still below the initial level, fourteen and sixteen minutes after the exercise. Moderately heavy work (type c) produces increase as well as drop of the fusion frequency.

TABLE IV

INFLUENCE OF SEX ON THE MAXIMUM DEVIATION OF THE FUSION FREQUENCY OF FLICKER AFTER 30 GENUFLEXIONS

1 Exercise	Sex	2 No.	3 Only increase	4 Increase and decrease	5 Only decrease	6 All increases	7 All decreases	8 Without change	9 Average	10 Diff.	$2\sqrt{SE_m^2 + SE_f^2}$
Genuflexions I	Men	25	19 = 76.0%	3 = 12.0%	2 = 8.0 %	22 = 88.0%	5 = 20.0%	1 = 4.0 %	+3.14		
	Women	29	15 = 51.7%	9 = 31.0%	4 = 13.8 %	24 = 82.7%	13 = 44.8%	1 = 3.4 %	+1.87	1.27	
Genuflexions II	Men	24	19 = 79.1%	3 = 12.5%	2 = 8.35%	22 = 91.6%	5 = 20.8%	0	+3.58		
	Women	23	12 = 52.3%	7 = 30.4%	3 = 13.1 %	19 = 82.7%	10 = 43.5%	1 = 4.35%	+2.33	1.25	
Total	Men	49							3.36		
	Women	52							2.08	1.28	1.399

fast, but the speed was not regulated. The average distance men ran until fatigue was 598 meters; that of women 331 meters. The difference (267 meters) was significant ($2\sqrt{SE_1^2 + SE_2^2} = 66.224$). The average speed of men was 282 cm. per second; that of women, 230 cm.; the difference (52 cm. per second) was significant (value of the expression: 20.72). Also the duration was significantly lower in women. This corroborates results of Metheny et al.,[12] who found the average endurance in running at constant speed on a treadmill half as much in a group of 17 women as in a group of 30 men.

In all types of exercise, "a," "c," and "d," the performance of women was smaller than that of men. No significant difference of the response of the fusion frequency of flicker could be seen in these types. It must be assumed, therefore, that the smaller amount of exercise elicited the same response in women as the greater amount of exercise did in men. In type "b" (genuflexions) the amount of work was the same for men and women. The average deviation of the fusion frequency of flicker after the exercise is +3.36 in men and +2.08 in women (total of all experiments, Table IV). The difference (+1.28) is somewhat smaller than the value of the expression (1.399), but both values are almost equal. Although the difference is not quite significant, there is an outspoken tendency to a higher increase of the fusion frequency in men than in women. The same tendency is reflected in the distribution of increase and decrease; 76 and 79 per cent of men (Series I and II, respectively) showed only increase (column 3) after the exercise, while only 52 per cent of the women reacted in the same way. Correspondingly, 20 per cent of men and 44 per cent of women showed a decrease of the fusion frequency (column 7).

DISCUSSION

There are four possible factors responsible for the deviation of the fusion frequency of flicker after muscular exercise.

1. *Circulation.*—The minute volume of blood flow increases during exercise, including the blood flow to the brain. In moderate exercise the oxygen demand of the brain is probably only slightly increased, so that the oxygen supply to the brain exceeds the oxygen demand. This improvement of oxygen supply is likely to increase the fusion frequency of flicker.

2. *Oxygen Debt.*—The huge oxygen debt after hard exercise expresses a general oxygen want including the brain tissue, i.e., the general oxygen demand exceeds the oxygen supply. This deterioration of the oxygen supply is apt to decrease the fusion frequency of flicker.

It is clear that factor "1" will prevail after moderate exercise, factor "2" after hard exercise such as running. This would explain the prevailing increase of fusion frequency after moderate work and the prevailing decrease after hard work.

3. *Radiation of Stimulation.*—A radiation of voluntary impulses from the motor centers to other parts of the central nervous system is generally assumed. This radiation, for instance, is believed to be responsible for the early stimulation of the respiratory center in muscular exercise. The existence of impulse radiation can be shown by the early increase of fusion frequency during static exercise (Fig. 1). The fusion frequency increased twenty seconds after the

onset of static exercise in 83 per cent of all observations. This time is too short to account for any circulatory factor. Radiation of stimulation should be assumed also in the other types of exercise, although it cannot be as readily demonstrated because of the longer duration of exercise and the later time of measurement of the fusion frequency. Although radiation of impulses can be demonstrated only in the early phase of exercise, before the possible interference of circulatory factors, there is no reason to believe that their existence is restricted only to that period. According to Allen and Schwartz's results, reflex stimulation or inhibition of the fusion frequency of flicker might be observed for several minutes after acoustical stimulation.

4. *Radiation of inhibition.*—It seems logical to assume a radiation of inhibition as well as radiation of stimulation from the motor centers. According to Wedenski[13] and Ukhtomski,[14] strong stimuli are likely to produce and spread inhibition to other parts of the nervous system, while moderate stimuli are likely to radiate stimulation. This, too, would explain the distribution of prevailing stimulation after short, moderate exercise and of prevailing depression after running.

The coexistence of nervous and circulatory factors would account for the complicated form of reaction (Fig. 1) after muscular exercise.

In earlier communications we have shown that subjective fatigue in types of work without muscular effort parallels rather closely the depression of fusion frequency of flicker. There is no reason to expect such close relationship between subjective fatigue and drop of fusion frequency after muscular work, because of the interference of muscular fatigue. Static exercise "a" was continued to subjective fatigue; nevertheless, it produced an increase of the fusion frequency of flicker, probably because the fatigue is localized in a rather small part of the central nervous system and because the increase of the oxygen demand is very slight. Certainly, the response of the fusion frequency of flicker does not depend only on the type and amount of exercise, but also on the state and condition of the central nervous system. In other words, the reaction to the same type of work will vary in the same subject when the condition of the central nervous system is altered. We have a chance observation to support this view. In a male subject of 37 years the pulley exercise was investigated two days after he had lost his father. He was in a state of depression and fatigue (due to the loss of sleep during several preceding nights). The exercise depressed the fusion frequency by −5.4 flashes. The test was repeated after two months, when the subject had overcome his depression and was in normal condition. At this time, he responded to the exercise with an increase of +5.2 flashes, which lasted for more than eight minutes.

From a practical point of view, these results indicate that a hard exercise of rather short duration may depress the state of the central nervous system for a comparatively long period of time. This explains the depressed capacity for mental work or other occupations involving nervous functions on the background of physical fatigue. Perhaps, this also accounts for the increased accident rate in fatigue, because of the probable deterioration of alertness. It can be concluded that in occupational work involving both muscular and nervous functions diminution of muscular fatigue will probably diminish

fatigue of the central nervous system. Short, moderate exercise may improve the state of the central nervous system. This would explain the favorable effect of gymnastics during rest pauses observed in several industrial plants. About 10 per cent of normal men and about 20 per cent of women, however, would probably react with depression even after short, moderate exercise. Therefore, a selection for this procedure is advisable. The selection could be made by using the fusion frequency of flicker.

SUMMARY

The reactions of the fusion frequency of flicker of 54 normal subjects after four different types of exercise of increasing severity ("a," static exercise; "b," 30 genuflexions; "c," pulley exercise; "d," running) were studied. Each exercise produced definite deviations of the fusion frequency of flicker. The majority of normal people (about 80 to 90 per cent) respond with an increase of the fusion frequency after static exercise and 30 genuflexions, and with a decrease of the fusion frequency after running. After pulley exercise, about 40 per cent of the subjects respond with both increase and decrease. The magnitude and the duration of the depression correspond to the severity of exercise. These results may explain the depressing effect of physical fatigue after severe muscular exercise, and the stimulating effect of short, moderate exercise on the state of the central nervous system. The endurance of women in static exercise, pulley exercise, and running is significantly lower than that of men, while there is no significant difference of the reaction of the fusion frequency of flicker. The response of the fusion frequency of women after an equal amount of work (30 genuflexions) appears to be inferior to that of men.

THE SIGNIFICANCE OF ERYTHROCYTIC PSEUDOAGGLUTINATION*

ROBERT D. BARNARD, M.D.,† CHICAGO, ILL.

PSEUDOAGGLUTINATION is a term used by Wiener[1] to designate all types of erythrocyte aggregation likely to cause confusion in the clinical determination of blood grouping. Included under this term, he lists rouleaux formation and the aggregation of erythrocytes which may be found in aged whole fluid blood ("autoagglutination").

The same term, pseudoagglutination, was used by Barnard[2] in connection with a certain type of aggregation observed when erythrocytes are acted upon by weak alkali. This type of aggregation appears to be due to a saponification of the cholesterol-lecithitides of the stroma causing the cells to stick together. It appears probable now that the "autoagglutination" of Wiener and the aggregation of rH-positive erythrocytes by the agency of anti-rH factor is of a similar nature, that the phenomenon may be produced by a variety of agents, and that pseudoagglutination, as latterly described, is a precursor to lipolytic hemolysis. For these reasons, it is suggested that the term, pseudoagglutination, be reserved for the specific prehemolytic process to be described, and for the purposes of distinction and that of classification pseudoagglutination may be compared with the other, better-known forms of erythrocytic aggregation; i.e., (1) rouleaux and (2) specific hemagglutination.

1. *Rouleaux*.—This is a physiologic process, having a definite teleologic role in the maintenance of capillary circulation. The mechanism underlying rouleaux is a physical one, as admirably demonstrated by the experiments of Kegerreis.[3] Rouleaux masses are unidimensional, the cell aggregates forming only by apposition of their biconcave surfaces, and the phenomenon, as would be expected from its physiologic nature, is entirely reversible. While this form of aggregation may be seen macroscopically, its designation, as rouleaux, is a microscopic procedure.

2. *Specific Hemagglutination*.—The mechanism of hemagglutination is immunologic. The aggregates are tridimensional, the clumps forming by indiscriminate apposition of groups of cells. Thus in an agglutinated mass, a single cell may be in contact simultaneously with many others, while in rouleaux, no erythrocyte may be in aggregated contact with more than two others. Hemagglutination is a completely irreversible process, and the agglutinated cells are morphologically and structurally altered as evidenced by their susceptibility to hemolytic agents. The designation of an aggregation phenomenon as a true agglutination may be made microscopically, but it is even more characteristic, when complete, on macroscopic examination.

3. *Pseudoagglutination*.—The mechanism appears to be chemical and to consist of a saponification of the cholesterol envelope. Thus, it can be pro-

Received for publication, February 16, 1943.

duced by dilute alkalis or, more rapidly, by toluene. The role of the latter, as a hemolytic agent, is by reaction with the cholesterol-lecithitides of the stroma. (Svedberg and Nichols,[4] 1927; Barnard,[5] 1940.) The cell membrane becomes sticky, and where erythrocytes come into juxtaposition, they tend to adhere. Since the greater proportion of contacts will be at the circumferential surface, pseudoagglutinative aggregates tend to be bidimensional. This is seen best in microscopic preparations with alkali as previously described,[2] and particularly if there are some cotton fibres in the field, the tendency of the cells to adhere to such fibres by their edges is clearly shown. At the same time, changes in the cell morphology under the influence of the hemolytic agent is evident; the cells swell, lose their biconcave shape, and gradually disappear along with liberation of the contained hemoglobin.

TABLE I

	DIFFERENTIATION OF ERYTHROCYTIC AGGREGATION		
	BOULEAUX	PSEUDOAGGLUTINATION	HEMAGGLUTINATION
Mechanism	Physical	Chemical	Immunologic
Aggregates	Unidimensional	Bidimensional	Tridimensional
Reaction	Reversible	Reversible or Irreversible	Irreversible
Change in Cell Morphology	None	Plasmolysis	Crenation
End Result	None	Hemolysis	Hemolysis (in vivo)
Best Determined	Microscopically	Microscopically	Macroscopically

By adjusting the concentration of alkali in which the erythrocytes are immersed, it is possible to demonstrate varying degrees of reversibility for this process. Extremely dilute alkali (1 to 3000 NaCN) will induce a type of aggregation remarkably similar in both microscopic and macroscopic aspects to that produced in rH-positive erythrocyte suspensions by anti-rH sera. Such aggregates may be broken up, after their formation, by vigorous agitation. Again, if such a suspension is allowed to settle in a test tube at room temperature, or if it is centrifuged, all cells are aggregated into a solid mass, but if the treatment be not too prolonged, the cell masses may be broken up by agitation. Since this sequence may be duplicated frequently in reaction mixtures of rH-positive cells and anti-rH sera, the concordance in their behavior between two supposedly diverse agents leads to the belief that, if pseudoagglutination is a precursor to hemolysis, the anti-rH factor is a *hemolysin* rather a true agglutinin. It remains to prove the major premise; the pseudoagglutination is indeed such a precursor, and to this end we have studied the pseudoagglutination produced by dextrose and that appearing spontaneously in aged, stored blood.

THE EFFECT OF DEXTROSE ON ERYTHROCYTIC AGGREGATION

Pendleton[6] reported an agglutinative action of concentrated dextrose or sucrose solutions on human erythrocytes. Such an action, he thought, might explain certain reactions occurring during the intravenous infusion of dextrose solutions. At the Cook County Hospital, we have routinely employed dextrose as a storage medium for blood for transfusion and had definitely demonstrated

that concentrations of dextrose up to 5 per cent (higher than could ever be sustained in vivo) were without any obvious effect on stored blood or its erythrocytes.* We had in fact demonstrated that somewhat higher concentrations of dextrose (12 to 20 per cent) completely inhibited the agglutination of erythrocytes by their own type-specific serum and that this inhibition was reversible in that the cells could be agglutinated when the concentration of dextrose was reduced. The inhibition of the interaction between specific hemagglutinin and hemagglutininogen (for this is what the action of dextrose proved to be) was masked in dextrose concentrations above 20 per cent by the phenomenon that Pendleton described, a phenomenon which has all the characteristics of pseudoagglutination and is invariably followed by hemolysis.

PSEUDOAGGLUTINATION OF ERYTHROCYTES IN AGED, STORED BLOOD

The blood bank has afforded the opportunity for observations on a large number of samples of stored, citrated dextrose-whole blood with regard to their tendency toward pseudoagglutination and hemolysis. While there is a considerable difference between individual samples in the rate at which either of these phenomena make their appearance, there is a distinct correlation between the two in any single specimen. After from one to twenty days of refrigeration, without agitation, the corpuscular layer will be a dark blue-violet color. While the supernatant plasma may show no evidence of hemolysis, it may have been proceeding for some time in the corpuscular layer, and the evidence thereof may have been confined to the corpuscular layer because of the low rate of diffusion of hemoglobin. If the cells in such a sample be suspended by gentle agitation, on their resettlement, free hemoglobin will be evident in the plasma. Such samples show many pseudoagglutinative aggregates.

Since hemolysis is present in these samples and may escape detection, except by allowing an inspection of the plasma after resuspension of the corpuscles, the need for inspection, in this manner, of stored whole bloods, before they are used for transfusion, is obvious.

In the main, samples of blood which showed early hemolysis would likewise show early pseudoagglutination, and this parallelism is carried over to bloods which reacted positively to the serologic tests that are supposed to be diagnostic of syphilis. Naturally these samples were never used for transfusion, even for a known syphilitic prospective recipient (on the theory that although it was not possible to give an individual more syphilis than he already has, he might be given a different kind), and consequently were subject to observation over a long period of time. Curiously enough, in serologically positive blood samples, both pseudoagglutination and hemolysis appeared to be markedly delayed.

It is true that many bloods exhibited gross hemolysis which seems to have occurred spontaneously in the stored samples without showing any pseudoagglutination, and the converse is also true: that samples exhibiting marked pseudoagglutination might show no greater tendency to hemolyze in the stored condition than unaltered bloods. In certain samples, the corpuscles will not mix diffusely with the plasma on agitation, but will swirl around in large tailed,

*It has been noticed, however that even 5% dextrose accelerates or facilitates the appearance of hemolysis in pooled, incompatible bloods.

discoid masses, the bidimensional nature of which is apparent macroscopically. These masses we formerly referred to as "clots" until they were found to be devoid of fibrin. The fibrinogen was still present in undiminished amount in the plasma, and these aggregations showed, microscopically, all the characteristics of pseudoagglutination. Before the nature of this aggregation was appreciated; because the erythrocytes could be separated by continued agitation and because the samples showed little or no hemolysis at this stage, some of these bloods were used for transfusion. The practice was discontinued because of the high incidence of severe hemolytic reactions.

From a practical standpoint, therefore, the presence of pseudoagglutination in a blood sample precludes the use of that sample for transfusion even though hemolysis may be absent. The pseudoagglutinated erythrocyte must be regarded as a potentially hemolyzed one, and the clinical significance of pseudoagglutination is identical to that of specific hemagglutination in incompatable blood.

SUMMARY

The term pseudoagglutination is restricted to a phenomenon observed in erythrocytes which have been acted upon by lipolytic hemolysins. Criteria are set up for its distinction from rouleaux and from specific hemagglutination.

Toluene, high concentrations of dextrose, and anti-rH factor action produce pseudoagglutination, which likewise appears spontaneously in stored whole blood.

Stored blood samples which show positive serologic tests for syphilis appear to be more resistant to spontaneous pseudoagglutination and hemolysis than do serologically negative bloods.

Pseudoagglutination is a precursor to, or a manifestation of, the initial stages of hemolysis by lipolytic agents.

Blood samples which show pseudoagglutination, even without manifest hemolysis, are unsuitable for transfusion.

THE OCCURRENCE OF A DOUBLE ZONE PHENOMENON IN ANTIHUMAN TISSUE SERUM*

Anderson Nettleship, M.D., Amsterdam, N. Y.

INTRODUCTION

DURING a group of experiments in which unperfused normal human kidney was injected into ducks, the duck serum was found to contain antibodies against human blood serum. This was not an unexpected result since the original material (antigen) contained some whole serum. Preliminary precipitin tests, however, showed such a well-defined double zone it was considered important to clarify its occurrence and if possible relate it to the proteins known to exist in human serum.

MATERIALS AND EXPERIMENTS

Normal human kidneys from acutely fatal trauma cases, in persons under the age of 40, showing no gross or microscopic changes beyond a mild degree of cloudy swelling, were removed within four hours of death; capsules stripped, and the kidney cut in long thin sections and frozen for twenty-four hours. After the pelvic fat was removed and the kidney ground fine, the pulp was suspended in minimal normal saline. Following an eight- to twelve-hour fat extraction (ether) in the cold, the water solution was precipitated with an excess of 80 per cent cold acetone. This precipitate, when resuspended in normal saline, proved fairly soluble. This precipitate was used to inject intravenously (3 c.c. to 4 injections) and intramuscularly (4 c.c. increasing to 10 c.c., 5 injections) in continuity every third day into adult Canton ducks. The fowls were bled on the tenth day following the last injection; the sera from 4 ducks were pooled and titrated against the following: (1) whole human blood precipitate (prepared similarly to the kidney precipitate except it had no fat extraction), (2) normal human sera, (3) whole *serum* precipitate (acetone precipitate in saline suspension), (4) erythrocyte cell stroma material, (5) hemoglobin, (6) globulin-free (Na_2SO_4 precipitated) serum. This wide variety of blood constituents was utilized in hopes of finding out what blood constituent was brought down in each precipitin zone. Results are given in Tables I, II, and III. Explanation of tables:

The antigen dilutions were made by mixing the antigen with normal saline, and diluting. The tests were run in 3 mm. diameter tubes, first putting the duck serum in and then the antigen with a capillary pipette. The tubes were water bathed four hours at 37.5° Centigrade and iceboxed over night. Readings were made in a reflected light against a concave mirror. In spite of attempting to layer the solutions, they did mix to some extent. Results are read from 0 to ++++ and where there was a ring it is shown thus ++°.

*Read by title, before the American Association of Pathologists and Bacteriologists, 42nd Annual Meeting, St. Louis, Missouri, April, 2, 1942.

This work was done while the author was Director of the Montgomery County Laboratories. At present, Passed Assistant Surgeon (R), U.S.P.H.S., Bethesda, Md.

Received for publication, February 18, 1943.

†Hemoglobin.
‡Serum albumin.

DISCUSSION

The duck serum tested contained a group of major antibodies against kidney substance, which are not discussed here, and minor antibodies. These minor antibodies, in varying dilutions, seemed to contain two entities, each with its distinctive optimal zone of precipitation. *When the duck antihuman serum was matched against whole blood precipitate, serum precipitate, or normal serum, the double zone made its appearance.* Red cell stromas (possibly globulins) gave a single precipitin zone as did hemoglobin. Their precipitins occurred in the zone of lower dilutions. Contrariwise, a globulin-free serum gave positive precipitins in higher dilutions. The precipitin reactions as seen from the tables were not always too clear cut, indicating that the precipitin method is more sensitive than the physical and chemical methods used to divide the compounds. As nearly as can be ascertained from published chemical data, the serum globulins are the larger, heavier molecular weight compounds, whereas, serum albumins are the smaller weight molecules.* These data, when fitted into the present precipitin system, show the larger molecular compounds combining in the lower dilutions, the smaller molecular weight compounds combining in the higher dilutions. Even though the antibodies are in the same solution, optimal zones of precipitation make their separation possible. The method may be useful in separating out unwanted antibodies where specific tissue-antibodies are to be studied.

*Svedberg, T., and Eriksson-Quensel, I. B.: Tabulae Biological Periodicae, V (4), 352 (1935-36). Quoted from Schmidt, C. L. A., The Chemistry of the Amino Acids and Proteins, Springfield, Ill., 1938, Charles C Thomas.

SUMMARY

Because of optimal precipitin conditions, it was possible to discover, in the minor antibody group of duck antihuman kidney serum, a double zone phenomenon. This phenomenon appears to rest upon the differential chemical structures involved. The higher molecular weight substances, the globulins, combine in the zone of lower dilutions. The smaller molecular weight albumins combine in the higher dilutions.

HEMATOLOGY OF THE PERIPHERAL BLOOD AND BONE MARROW OF THE DOG*

EDWARD J. VAN LOON, PH.D., AND BYRON B. CLARK, PH.D.
ALBANY, N. Y.

WITH THE TECHNICAL ASSISTANCE OF DOROTHY BLAIR

NORMAL values for peripheral blood of dogs have been reported by a number of investigators[1-13] (and others); however, the available data is still comparatively small. Only three reports of differential bone marrow counts were found.[14-16] In the course of several investigations considerable data have been obtained on normal values for peripheral blood of the dog together with some observations on bone marrow, and we are presenting a summary of this data.

METHODS

Adult mongrel dogs of both sexes weighing 8 to 25 kg. were used and all received our standard kennel ration. The animals were trained to be tied down and were allowed to remain quiet for some time before withdrawing the blood samples, which were obtained from the femoral artery at approximately the same hour of the morning. A mixture of dried ammonium and potassium oxalate was used as the anticoagulant. The blood was drawn into Thoma certified pipettes and diluted with Hayem's solution for the erythrocyte counts, and 1 per cent acetic acid solution tinted with gentian violet for the leucocyte counts. After hand shaking the pipettes for at least three minutes, a few drops were discarded, the hemocytometers filled (certified Levy-Hausser chambers with Neubauer rulings), and duplicate counts were made.

Smears for the leucocyte differential and reticulocyte counts were made initially by both the slide and coverslip methods, but the latter is now used exclusively since a better distribution of cells is obtained. Two hundred cells were counted for the leucocyte differential. The smears for reticulocytes were prepared after staining with brilliant cresyl blue, and at least 500 red cells were counted. Occasionally the wet mount technique was employed. Wright's stain was used for the leucocyte smears and for counterstaining the reticulocyte

*From the Department of Physiology and Pharmacology, Albany Medical College, Union University.
Received for publication, March 1, 1943.

smears. Cell volume was determined in duplicate with Wintrobe tubes.[17] Hemoglobin was determined by the Evelyn spectrophotometric method.[18]

Bone marrow samples were obtained immediately following sacrifice of the animals. Three different types of preparations were made: (1) Transverse sections were sawed from the upper third of the femur, and the marrow was shelled out of the bony ring, fixed in Zenker's formalin, sectioned, and stained with hematoxylin and eosin. (2) Impression imprints were made from femur marrow tissue and stained with Wright's or Giemsa's stain. (3) Marrow samples extruded from rib sections were diluted with heparin or heparinized serum, cover slips smears prepared, rapidly dried, and stained with Wright's or Giemsa's stain.[19] Differential counts of 500 or 1000 cells were made on the two latter types of preparations.

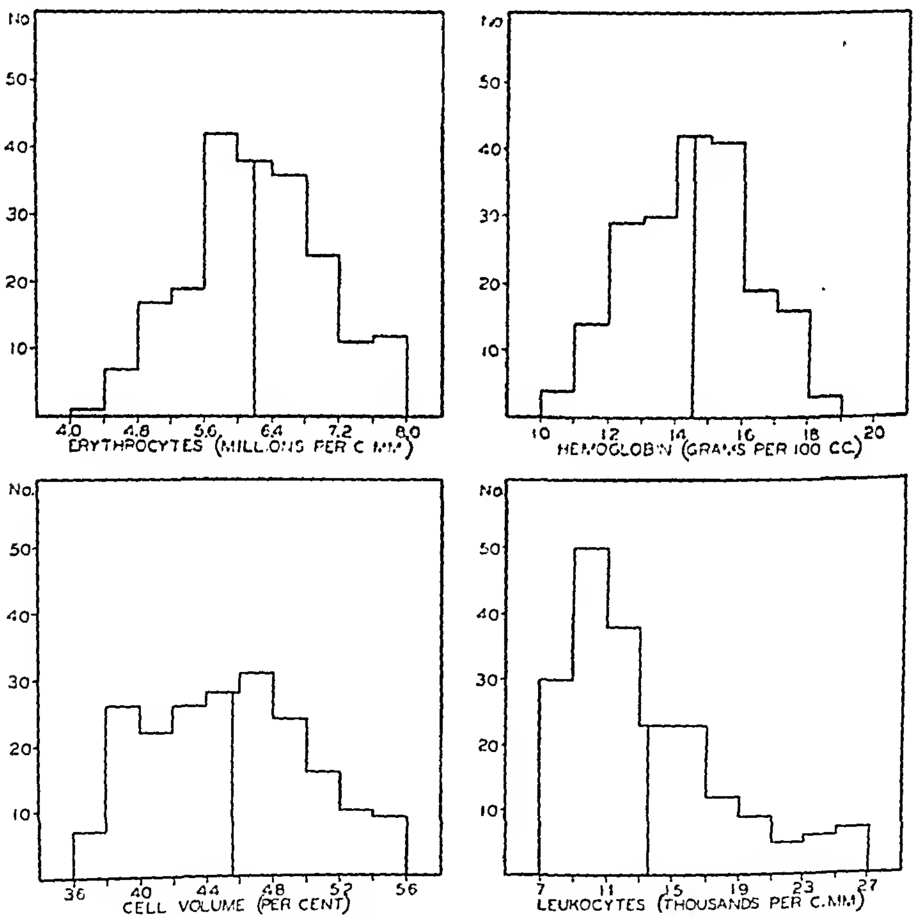

Fig. 1.—Frequency histograms of the hematology of 81 dogs.

RESULTS

Our observations on peripheral blood were made on 81 dogs and include 207 erythrocyte counts, 120 reticulocyte counts, 203 leucocyte counts, 199 determinations of cell volume, 198 determinations of hemoglobin, and 196 differential leucocyte counts. The observations on most individual animals were made during a period of one to two months; in 11, however, they extended over

a period of several months. The observations on the red and white blood cell counts, hemoglobin, and cell volume have been grouped in 2 ways, statistically analyzed, and are presented in Table I. All determinations on the 81 dogs are included in part A, and frequency histograms are shown in Fig. 1. Calculation from the mean values reveals a mean corpuscular volume of 73.4 cubic microns, a mean corpuscular hemoglobin of 23.7 micromicrograms, and a mean corpuscular hemoglobin concentration of 32.3 per cent. In part B the results of taking a single observation on each dog are shown; the last determination which had been made was arbitrarily chosen. These data are not significantly different, thus showing that an unequal number of determinations on some of the animals did not materially influence the analysis in part A. We noted that there was a general tendency for the erythrocyte, hemoglobin, and cell volume values to decrease slightly when the observations were extended over a long period. This trend was more definite in the first few weeks and was considered a result of training.

TABLE I

STATISTICAL ANALYSIS OF PERIPHERAL BLOOD HEMATOLOGY

		MEAN	STANDARD DEVIATION	PROBABLE ERROR OF MEAN	COEFFICIENT OF VARIATION	NO. OF OBSERVATIONS

*Mean values found by this laboratory.

The mean values of our data, compared with some of those reported in the literature, are shown in Table II. Our results are in general agreement with those of Bruner, et al.,[5] Mayerson,[11] Morris, et al.,[12] and others.

It was noted in making the reticulocyte count by both the wet and dry methods that there were many instances in which no reticulocytes were seen in counting 500 erythrocytes. Further examination of the smears, however, always revealed the presence of some reticulocytes.

We have observed, as others have reported, that no significant difference exists between the values obtained for males and females, for the different breeds, and that age apparently has little or no effect after the animals are 10 to 12 months old.

The mean and range of bone marrow differential counts on rib smears and femur imprints on the same eight dogs are shown in Table III. The impression imprints probably give a more nearly physiologic distribution of marrow cells. These preparations are difficult to prepare, however, do not stain well, and the counts obtained are somewhat selected, since usually only those cells on the periphery of each imprint can be differentiated. Smears from extruded rib marrow are easy to prepare, stain well, and cells over the entire smear are readily differentiated. It is our impression that representative marrow counts are obtained from these smears.

TABLE III

BONE MARROW DIFFERENTIAL COUNTS

TYPE OF CELL	RIB SMEARS		FEMUR IMPRINTS	
	MEAN	RANGE	MEAN	RANGE
Myeloblasts	0.6	0.2- 1.0	0.5	0.2- 1.0
Promyelocytes	1.6	0.7- 2.8	0.8	0.2- 1.1
Myelocytes	6.0	2.7-10.0	4.6	1.7- 8.0
Metamyelocytes	3.4	1.1- 4.6	3.3	2.0- 4.3

Megakaryocytes	0.5	0- 1.4	0.2	0- 0.3
Unclassified		0.8- 1.4		0.4- 3.1

Comparison of the data on rib smears with those on the femur imprints reveals a close similarity. Stasney and Higgins[15] have already pointed out that marrow from the rib, proximal femur, and middle femur show essentially the same general trend in the relative percentage of distribution of cells, although the myeloid-erythroid ratio is somewhat higher in the rib. Our mean myeloid-erythroid ratio is slightly over one (range 0.6 to 2.4), thus agreeing with the data of Mulligan[16] and Alexandrov.[14] Stasney and Higgins found the myeloid-erythroid ratio consistently below one; however, their mean erythrocyte count was only slightly above 5.0 million. These observations lend further validity to the rib smear technique.

Histologic examination of the femur marrow sections revealed a wide variation in total cellularity. In general, active hematopoietic tissue was found around the periphery of the section and as small islands among the fat cells which filled the center of the section.

SUMMARY

A summary and statistical analysis of the data on the peripheral blood hematology of 81 dogs are presented. Differential cell counts of rib and femur marrow preparations from 8 dogs are included.

The authors are grateful to Dr. J. L. Schwind of the Department of Anatomy for many helpful suggestions.

EFFECTS OF SULFAPYRAZINE AND SULFADIAZINE ON MICE INFECTED WITH HEMOLYTIC STREPTOCOCCUS, PNEUMOCOCCUS, AND STAPHYLOCOCCUS AUREUS*

George W. Raiziss, Ph.D., M. Severac, M.D., and J. C. Moetsch, Philadelphia, Pa.

SUBSTITUTION of sulfanilamide in the sulfonamide group by replacement of one of the hydrogens by various heterocyclic compounds resulted in some cases in a substantial enhancement of therapeutic activity. The heterocyclic part of sulfadiazine, therapeutically a very active compound, consists of the pyrimidine ring where the 2 nuclear nitrogens are in the meta position to each other. Raiziss and Clemence[1] described a derivative containing a heterocyclic with 2 nuclear nitrogens in the para position. The same product was prepared independently by Elligson.[2] This derivative was obtained by the interaction of para-acetylaminobenzene sulfonyl chloride with 2-aminopyrazine. For the sake of brevity we named this product sulfapyrazine.

Sulfapyrazine has already been investigated clinically in the treatment of pneumonia and reported by Ruegsegger, Hamburger, Turk, Spies, and Blankenhorn.[3] The authors stated that 22 selected patients who received the drug by mouth showed prompt improvement and ultimate recovery with no significant signs of toxicity.

We are presenting studies on toxicity and blood levels and also on the therapeutic effect of sulfapyrazine in mice infected with various pathogenic organisms.

TOXICITY

Mice were fed a drug food diet containing ¼, ½, ¾, and 1 per cent of sulfapyrazine or sulfadiazine for a fourteen-day period. We have determined that mice consume on an average 4 Gm. per day of the drug diet. This would be equivalent to 0.010 Gm. of drug in ¼ per cent diet; 0.020 Gm. in ½ per cent; 0.030 Gm. in ¾ per cent; and 0.040 Gm. in 1 per cent. Table I shows that ¼ and ½ per cent drug diets containing either sulfapyrazine or sulfadiazine were well tolerated when fed for a period of fourteen days. Three-fourths per cent diet was tolerated only by 60 per cent of animals; 1 per cent diet of sulfapyrazine was tolerated by 50 per cent of animals at the end of fourteen-day period, while on a 1 per cent sulfadiazine drug diet all animals died after nine days of feeding.

BLOOD LEVEL DETERMINATIONS

Blood levels were determined by Bratton and Marshall's method.[4] From Table II it is apparent that sulfapyrazine on various drug diets produces com-

*From the Dermatological Research Laboratories, Philadelphia, Division of Abbott Laboratories, North Chicago.

A preliminary paper was presented before the Federation of American Societies for Experimental Biology at Boston, Mass., March 27, 1942, by the senior author (G. W. R.)

Received for publication, March 1, 1943.

paratively high blood levels in mice ranging from 7.2 to 32 mg. per 100 c.c., which, however, are lower than those obtained with the respective sulfadiazine feedings.

COMPARATIVE THERAPEUTIC EFFECTS OF SULFAPYRAZINE AND SULFADIAZINE

In all of the therapeutic experiments drugs were administered to mice in food according to the method described by Litchfield, White, and Marshall.[5]

Mice were infected with the *Streptococcus hemolyticus* strain C203 using 1000 minimum lethal doses containing from 5 to 10,000 bacteria. According to Table III sulfapyrazine exerted a better therapeutic effect than sulfadiazine on mice with streptococcus infection fed the ¼ per cent drug diet. On the ½ per cent drug diet sulfadiazine gave better results than sulfapyrazine. Under the same condition, sulfanilamide proved to be less effective.

TABLE II

AVERAGE OF DAILY RECORDED BLOOD LEVELS IN MICE FED DRUG DIET FOR 10 DAYS

PER CENT DRUG IN FOOD	BLOOD CONCENTRATIONS SULFAPYRAZINE MG. PER 100 C.C.*	FREE DRUG SULFADIAZINE MG. PER 100 C.C.*
¼	7.2	15
½	10.4	26
¾	28	38
1	32	43

*The averages represent tests using from 4 to 6 mice.

TABLE III

COMPARATIVE THERAPEUTIC EFFECT OF SULFAPYRAZINE AND SULFADIAZINE DRUG ADMINISTERED WITH FOOD FOR TEN DAYS

STREPTOCOCCUS HEMOLYTICUS INFECTION, STRAIN C203

	Sulfanilamide	25	84	84	68	60	60	60	60	56	56	56
	Controls	27	4	0								

Heart cultures of autopsied mice who died before the 28th day invariably were positive for Streptococci.

In the experiments on Type I pneumococcus infection we used strain M-36.[6] Mice were infected with 10 minimum lethal doses, the total content of inoculum being about 100 bacteria. This strain proved to be of high virulence. As seen from Table IV, 88 per cent of mice on the ¼ per cent sulfapyrazine diet survived seven days. After fourteen days the survival rate dropped to fifty per cent. On ¼ per cent sulfadiazine diet, 33 per cent of mice survived seven days and after fourteen days 23 per cent, indicating a better effect for sulfapyrazine. On a ½ per cent drug diet sulfadiazine was somewhat less effective than sulfapyrazine.

In our experiments on Type II pneumococcus infection, we used strain M-48 as described in previous publication.[6] Mice were infected intraperitoneally with 10 minimum lethal doses containing about 250 bacteria.

From Table IV one can see that mice fed ¼ per cent of sulfapyrazine diet showed 96 per cent survivals after four days, 44 per cent after fourteen days and 40 per cent after twenty-eight days of observation.

Under the same conditions, sulfadiazine therapy resulted in 33 per cent survivals after four days and only 5 per cent survivals after fourteen and twenty-eight days. On ½ per cent diets both drugs after twenty-eight days gave equally good therapeutic results.

Pneumococcus Type III proved to be more resistant to drugs than Type II. We used 10 minimum lethal doses which contained about 200 bacteria of strain M-50. With a ¼ per cent diet, 20 per cent of the mice fed sulfapyrazine survived three days, while at the end of twenty-eight days 5 per cent survived. Mice given ¼ per cent sulfadiazine diet showed about the same results with a survival rate of 20 per cent after three days and 7 per cent at the end of twenty-eight day period.

		Controls	17	18	0								

Heart cultures of autopsied animals invariably were positive for Pneumococci.

On the ½ per cent diet at the end of three days sulfapyrazine had 70 per cent, while sulfadiazine had only 55 per cent survivals. At the end of twenty-eight days, 38 per cent survivals were observed with sulfapyrazine and only 25 per cent with sulfadiazine. In this case sulfapyrazine showed better therapeutic effect.

Staphylococcus aureus infection was produced in mice by the intravenous administration (saphenous vein) of 0.2 c.c. of a saline suspension containing about 8 billion bacteria. This culture had five passages through mice prior to its use. As seen from Table V, 50 per cent of control mice died at the end of seventy-two hours and the rest died seven days after infection.

On a ¼ per cent sulfapyrazine diet, 40 per cent of the animals survived for eleven days and 30 per cent survived fourteen days, showing a slightly better effect than sulfadiazine.

On a ½ per cent drug diet, sulfadiazine proved to be better.

Cultures of kidneys of autopsied animals were positive for *Staphylococcus aureus.*

DISCUSSION

(a) Sulfapyrazine, an isomer of sulfadiazine, by this and further investigations may prove to possess certain advantages over sulfadiazine in clinical application and, therefore, may be valuable.

(b) We have established that blood levels of mice kept on drug diets containing sulfapyrazine are generally lower than those of sulfadiazine, being higher than blood levels obtained with other sulfanilamide derivatives.

(c) This report is the first, according to our knowledge, of an extensive study of sulfapyrazine by the food drug diet method on various types of pneumococcus.

(d) By a careful series of experiments, we established that sulfapyrazine has either equal or somewhat better therapeutic effect on food drug diets at lower blood levels than sulfadiazine.

CONCLUSIONS

1. Mice tolerate sulfapyrazine and sulfadiazine on a 1/4 and 1/2 per cent food diet equally well, while a 3/4 and 1 per cent drug diet sulfapyrazine is somewhat better tolerated than sulfadiazine.

2. Blood levels on 1/4 and 1 per cent drug diets ranged from 7.2 to 32 mg. per 100 c.c.

3. In beta-hemolytic streptococcic infection both drugs were of equal therapeutic effectiveness.

4. In Type I Pneumococcus infection, mice fed on 1/4 and 1/2 per cent sulfapyrazine drug diets showed a better survival rate.

5. In Type II pneumococcus infection, sulfapyrazine showed a greater survival rate, than sulfadiazine on 1/4 per cent and equal on 1/2 per cent drug diets.

6. In Type III pneumococcus infection both drugs were equally effective on the 1/4 per cent diet, while sulfapyrazine gave better results on a 1/2 per cent diet.

7. According to our experiments, in *Staphylococcus aureus* infection, sulfapyrazine and sulfadiazine proved to be equally effective.

A NEW METHOD FOR THE EVALUATION OF DRUGS AFFECTING THE REACTION OF MICE TO PAIN STIMULATION*

KENNETH KUETER, B.S., AND RICHARD K. RICHARDS, M.D., NORTH CHICAGO, ILL.

IN recent years a number of new methods for the testing of analgesic drugs in animals has been reported. Without claim for completeness we mention here the methods of Macht and Macht,[1] d'Amour and Smith,[2] and of Andrews and Workman,[3] the last two methods being modifications of the principle developed by Hardy, Wolff, and Goodell.[4] In our experience, results can be obtained with all of them. We found that there was little consistency, however, inasmuch as certain drugs were found relatively more potent with one of the methods than with another. On account of this we employ as a rule several procedures in estimating analgesic properties.

The necessity of immobilizing the animal during the test represents, in our opinion, a common disadvantage of these methods. Since it is not certain whether any method of determining analgesia in animals measures "pain" in the sense of the human quality or just a reflex, we believe the experimental conditions should enable the animal to be as unrestricted in its movements as possible.

This demand is satisfied in a procedure used by Straub and Triendl[5] and based upon a method developed by Forst,[6] which consists essentially of having a mouse move about freely on a disc and measuring the movements by means of a work adder; a clamp is then applied to the nose or rectum and the reaction is measured by the increased activity of the animal. We found it profitable to substitute the continuous stimulation caused by the clamp by an intermittent stimulation which can also be easily varied in degree. Our procedure does not require complicated or expensive apparatus and has proved valuable in our hands in combination with other methods.

METHOD

Mice are used for this test. The animals are stimulated through their feet in a basket made of plasteele and aluminum with a bottom made of lightweight

bakelite. The basket resembles a small hatbox. It is 17 cm. in diameter and 9.5 cm. in height. The bottom of the basket is covered with rows of fine copper wire about 3.0 mm. apart. These wires are strung across the bottom so that one wire is positive and the adjacent one negative. This is accomplished by stringing one continuous wire in rows about 6 mm. apart and then stringing another wire in between the rows of the first strung wires. Care must be taken so that the two wires are well insulated from each other. (Fig. 1 shows how this is accomplished.) The basket is suspended from a bellows made by stretching a condom over a large-sized heart chamber. The basket hangs by means of strings and a wire hook made fast in a small, square cardboard and fastened to the condom with rubber cement. The heart chamber is connected to a tambour and writing arm with rubber tubing. The tambour is held in place by a clamp and ring stand. Any movement in the basket sends air impulses through the tubing to the tambour and arm. Movements of the animal are recorded on a slowly moving kymograph. The basket is connected to the secondary coil of a Harvard inductorium, and the primary (4 volts) current is made intermittent by means of a Harvard electric time clock or metronome. The physical considerations of the Harvard inductorium are explained in detail by Macht and Macht.[1] (Fig. 2 shows the complete apparatus.)

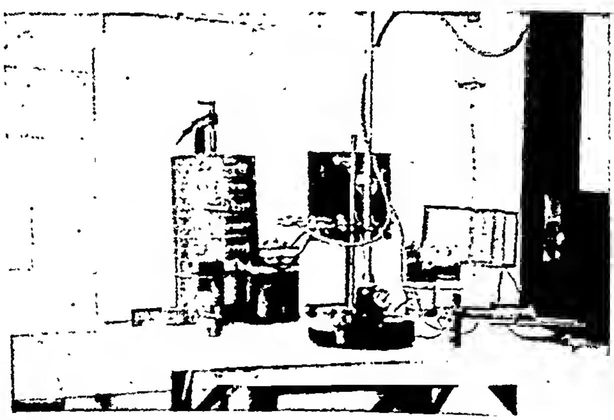

Fig. 2.

At least two mice are run on a dose level. The animals are first tested as normal mice. A tracing is always made with no stimulation, covering about one inch of paper. Then, the secondary coil is set at 7 cm., and the time clock is set in motion. A short tracing is made and the current is shut off. The secondary coil is then moved to 6.75 cm. A tracing is made, the current interrupted, the coil shifted to 6.5 cm., and so on, in 0.25 to 0.5 cm. intervals. As the stimulus becomes stronger, the mice start to make jumping movements which increase to a maximum, usually at about 5.5 to 4.0 cm. secondary coil distance. There is a considerable variation in the sensitivities of the individual animals that has to be taken into consideration for the evaluation of an analgesic. Mice which fail to show an increment of reaction with increased stimulation or are too restless are discarded.

After the normal reactions of the mouse have been recorded, the drug under investigation is administered either by mouth or by intraperitoneal injection. For the first test we give usually 25 to 50 per cent of the L.D.50. Later the dose has to be adjusted according to experience. Tests are made in intervals of 20, 30, or 60 minutes depending on the type of drug and method of administration. Fig. 3 shows tracings of such experiments, and a summary of the effects of a few well-known analgesics administered orally is given in Table I; the columns headed "Centimeter" show the reading of the secondary coil at which a definite stimulation was recorded after the drug. Necessarily, this criterion is somewhat subjective with the individual investigator, but if interpretations are always made on the same basis, the results become comparable. Table II shows the effects of morphine by intraperitoneal injections. Whereas the sensitivity of this method compares favorably with other procedures, we failed to obtain a definite analgesic effect with aspirin after oral administration with the chosen dose, but phenacetin and amidopyrine exhibited definite analgesic action. Nembutal was ineffective at 55 mg./kg., a dose not producing marked depression. Analgesia appeared with the definitely depressing dose of 75 mg./kg. and became complete with 110 mg./kg. In this stage no reaction was elicited. This proves that our method of stimulation produces central effects and not merely peripheral con-

traction by means of peripheral stimulation. Newer drugs which were tested and found analgesic by this procedure have proved to be effective in preliminary clinical investigations.

We are aware that, in testing of analgesic drugs, not only their central true analgesic action but also other effects have to be taken into consideration. Thus, morphine possesses a definite stimulating effect upon the spinal centers, an action which results in the well-known Straub phenomenon; however, in our test, signs of the spinal stimulation do not show up (*see Fig. 3, upper tracings*). The analgesic effect of aspirin, so conspicuous in humans, appears to be difficult to demonstrate in animals. This has been substantiated recently again by Smith, D'Amour, and D'Amour.[7] The barbiturates which exert a general cerebral depressing effect fail to influence selectively the pain centers, as is demonstrated by our failure to obtain analgesic effects with sedative doses; this is in agreement with clinical experience. Taking all these factors in consideration, one has to recognize the limitations of new methods endeavoring to measure a particular property in the presence of other factors which will influence a test.

We believe that the above described method will be of help to investigators in this field in conjunction with other procedures. The absence of restraint exerted on the animals, the recording of the reactions of the animals, and the possibility of using large numbers of small animals have definite advantages. The apparatus needs little care, but the basket should be inspected frequently and urine and feces should be removed to prevent short circuit. The air transmission system must of course be leakproof and should be adjusted to optimal sensitivity.

SUMMARY

A new method for testing analgesic drugs in mice is described. The method permits the application of an intermittent and increasing stimulus to mice without restriction of their movements and obtains direct records of their reactions.

CHRONIC INDURATIVE PNEUMONIA RESULTING FROM CARDIOSPASM*

A Case With Nonpathogenic Acid-fast Bacilli in the Sputum

Frederick C. Warring, Jr., M.D., and Arnold B. Rilance, M.D., Shelton, Conn.

PNEUMONITIS complicating cardiospasm does not appear to be a very common condition. Isolated cases have been reported.[1, 2] On the other hand, Sturtevant,[3] in an article reviewing the literature on cardiospasm, fails to mention pulmonary complications, apparently because of their rarity. Even more uncommon have been reports of the isolation of nonpathogenic acid-fast organisms from the sputum in this condition. Baldwin[4] has recently reported such a case, and a similar one has been described by Cummins and Williams.[5] These two cases are apparently the only ones to be found in the literature in which nonpathogenic acid-fast bacilli have been found in the sputum in this condition. A third case has lately come under our observation.

CASE HISTORY

G. H., a white female, single, aged 65 years, a bookkeeper, was admitted to the Laurel Heights State Tuberculosis Sanatorium on December 8, 1941. There was no history of exposure to tuberculosis.

Past History.—In 1922 the patient began to have difficulty in swallowing, with regurgitation of small amounts of food, but not of whole meals. There was no history of having swallowed any irritants. At that time she manifested mild jaundice, and her gall bladder, containing stones, was removed. Further studies while she was in the hospital revealed moderate cardiospasm. No dilatation was then felt to be necessary.

During the past twenty years she has been troubled by this regurgitation for periods varying in length from a few hours to three days, and then would be entirely free from this symptom for intervals up to several months. She denied aspirating vomitus at any time.

Present Illness.—Gradually, over the past year and a half, there has been a loss of 16 pounds in weight. This was probably because she ate only small amounts of food in an effort to ward off regurgitation. Seven weeks before admission the patient developed weakness, fever, and night sweats. She also began to cough, and she raised some mucoid sputum which was not foul but did contain a few food particles. On bed rest at home she failed to improve and came to Laurel Heights on December 8, 1941.

On admission her general condition was poor. Her best previous weight had been 136 pounds, but she was now down to 87. Stereoroentgenograms of the chest, taken on December 9, 1941, showed mottled densities throughout the lung field on the right, with consolidation from the level of the third to the seventh vertebral spines. On the left, there were conglomerate patches in the lower lobe (Fig. 1.). Physical examination was noncontributory, except for the lungs. There were signs of infiltration, with medium and fine râles, over the areas of disease seen in the x-ray.

The patient had asymptomatic *Bacillus coli* bacilluria, with white blood cells, but no other urinary abnormalities. Hemoglobin was 11.5 Gm. (74 per cent); red blood cells, 3.85; white blood cells, 16,500, with polymorphonuclear cells 85 per cent, lymphocytes 9 per cent,

Received for publication, March 10, 1943.

monocytes 5 per cent, and eosinophils 1 per cent. Sedimentation rate (Cutler) was 27.0 and 28.5 mm. Kline diagnostic test was negative. A tuberculin test was highly positive to the second strength of purified protein derivative.

X-rays of the stomach and intestines were negative. Barium was retained in the esophagus, however, for as long as ten hours, revealing obstruction at the cardiac orifice. The lower third of the esophagus was mildly and uniformly dilated. No diverticulae could be seen (Fig. 2).

The patient was felt to have a cardiospasm of twenty years' duration. By unconsciously aspirating food, probably during sleep, she had developed a chronic, bilateral induration pneumonia.

Two specimens of sputum, raised from the lungs, contained large numbers of acid-fast bacilli. Morphologically these were very similar to tubercle bacilli. The working diagnosis of aspiration pneumonia led to further studies which demonstrated the organisms to be nonpathogenic, acid-fast saprophytes.

Fig. 1.—X-ray of the chest on admission 12/8/41.

On bed rest the patient ran a continuous fever from 100° to 101° F. Her pulse ranged from 75 to 85. During her two months' stay in the Sanatorium there was no significant change in the appearance of serial x-rays of the lungs. Occasional regurgitation persisted, but she gained a little in weight and strength. On February 12, 1942, she was discharged, to receive treatment elsewhere for the cardiospasm.

In March, 1942, Miss H. was treated by Doctor Norton Canfield at the New Haven Hospital. Dilatation of the lower end of the esophagus was accomplished by means of the McKenzie dilator. After two weeks, good esophageal function was obtained. Since that time she has been able to swallow and retain both liquids and solid foods without difficulty.

The patient returned to our Out-patient Department for a check-up on October 9, 1942. Her general condition was much improved and she had gained about twenty pounds. She felt

stronger, her fever had disappeared, and she had practically no cough or expectoration. Chest roentgenograms showed pronounced clearing of the densities in both lungs, although a good deal of chronic, fibrous infiltration remained (Fig. 3). No acid-fast organisms could be demonstrated in the sputum by smear or culture at this visit.

Fig. 2.—X-ray taken 10 hours after barium meal showing cardiospasm.

THE ORGANISM

On admission, in December, 1941, acid-fast rods were found in good numbers in the sputum on direct smear. Morphologically they closely resembled tubercle bacilli, although a few acid-fast coccoid bodies were also present. The organism grew well in Hamburg broth in twenty-four hours. On dextrose agar, after forty-eight hours, the colonies were smooth and had a slight cream color, taking on an orange tinge as the culture aged. No carbohydrates were fermented. After several subcultures the morphology changed markedly. The rods disappeared, leaving mostly acid-resistant, deep-staining, coccoid bodies, with some fine, faintly staining filamentous forms. Guinea pigs inoculated with the bacteria did not develop tuberculosis, nor did they become sensitized to old tuberculin.

Doctor Friend Lee Mickle of the Connecticut State Laboratory and Mr. William Steenkin, Jr., at the Research and Clinical Laboratory of Trudeau, New York, studied these cultures with us. It was agreed that the organism was a nonpathogenic acid-fast saprophyte.

Doctor Edward R. Baldwin of Saranac Lake, New York, made a tuberculin from cultures of this saprophyte. Skin-tested with 0.1 mg. of this autogenous tuberculin, the patient reacted with an area of erythema measuring 3.5 × 4.0 cm. and marked induration. An intradermal control test, using 0.1 mg. of old tuberculin, produced an area of erythema 4.5 × 6.5 cm. with pronounced induration.

Twelve other patients with proved, active pulmonary tuberculosis were skin-tested, using 0.1 mg. of the autogenous tuberculin in six patients and 1.0 mg. in the remaining six. Only two patients, both of whom received the 1.0 mg. dose of the autogenous tuberculin, showed a mild, but typical positive reaction, with erythema and induration. All twelve cases reacted strongly to 0.1 mg. of regular old tuberculin.

Fig. 3.—X-ray of the chest taken on 10/9/42, seven months after treatment of cardiospasm by dilatation. Moderate clearing of infiltration in both lungs.

These studies showed that the patient had acquired a marked degree of sensitivity to the nonpathogen in her sputum. Almost complete lack of reaction in the tuberculous controls demonstrated that this could not be explained adequately by cross sensitivity.

COMMENT

This report of another case of aspiration pneumonitis, secondary to cardiospasm, in which acid-fast bacilli have been found in the sputum, would suggest

a relationship that is more than accidental. As proposed by Baldwin,[4] a logical explanation for the source of the nonpathogenic acid-fast bacilli is to be found in the aspiration of food particles from the esophagus into the lungs. There the organism may become established and occasionally make its appearance in the sputum. Similar nonpathogenic acid-fast organisms have been cultured from many raw fruits and vegetables.[4]

The question arises whether or not this acid-fast saprophyte had developed some slight degree of pathogenicity for this particular patient. Probably not, since it did not seem to influence the course of the aspiration pneumonia and did not produce disease in guinea pigs. On the other hand, it appears that the bacteria did not merely lodge inertly in the bronchial tree, but established themselves as facultative parasites. This assumption is supported by the development of the marked sensitivity, absent in controls, to the tuberculin prepared from the acid-fast bacilli in her sputum.

The finding of these acid-fast rods in the sputum on direct smear is of definite interest. The differentiation between them and tubercle bacilli on the basis of their morphologic characteristics would be extremely difficult. Thorough bacteriologic studies should be performed on any patient suspected of having an aspiration pneumonitis, in which acid-fast organisms are found in the sputum. Otherwise a mistaken diagnosis of pulmonary tuberculosis may readily be made.

The short length of time during which the acid-fast bacilli were found in the sputum and the rapidity with which they changed to coccoid forms may explain why more of these cases have not been reported. Apparently only under certain favorable cultural environments do they retain their acid-fast bacillary form. This is true both in vivo and in vitro. The rapidity with which the organism multiplies (twenty-four to forty-eight hours) on most laboratory media is one means of differentiating them from tubercle bacilli.

SUMMARY

A case of aspiration pneumonitis resulting from cardiospasm is reported, in which saprophytic acid-fast bacilli were found by direct smear in the sputum. Morphologically these bacteria resembled tubercle bacilli. The bacteriologic characteristics of the organism are described.

CLINICAL CHEMISTRY

STUDIES IN PROTHROMBIN: V. ARTERIAL AND VENOUS PLASMA PROTHROMBIN TIME IN MAN*

SHEPARD SHAPIRO, M.D., NEW YORK, N. Y.

THE liver is essential for the elaboration of prothrombin.[1] Although other tissues seem not to be involved directly in the process, nevertheless, recent observations suggest that under certain conditions additional mechanisms might contribute toward the maintenance of prothrombin at a level (or activity) higher than normal. Thus, hyperprothrombinemia has been demonstrated in (a) acute thrombophlebitis and the initial stage of thrombo-embolization[2, 3] and (b) multiple myeloma.[3]

It has been noted by Andrus, Lord, and Kuner[4] in 17 out of 20 experiments on dogs that blood obtained from the left ventricle exhibited less prothrombin activity than that removed from the right ventricle. The average difference was 10.6 per cent, determined by the two-stage method of Warner, Brinkhous, and Smith.[5] The visceral and peripheral arterial and venous bloods showed no significant difference.

These observations led to the present investigation to determine what is the relationship between the peripheral arterial and venous blood plasma prothrombin time in man.

The prothrombin times of arterial and venous plasma of twenty-six patients were studied. In 11 of these, the venous plasma prothrombin times were normal; in the remaining 15, the prothrombin times were prolonged as a result of existing liver disease, nutritional (vitamin K?) deficiency, or therapeutic agents which decrease the level (or activity) of prothrombin (salicylates, sulfanyl compounds, Dicumarol).

Method of Prothrombin Assay.—The procedure used to estimate the prothrombin time is based upon the single-stage method of Quick[6] and includes estimation of the prothrombin time of whole and diluted (12.5 per cent) plasma. The rationale, clinical and experimental applications have been set forth in previous communications.[2, 3, 7-11] The greater sensitivity of 12.5 per cent plasma over that of whole plasma also has been demonstrated.[12, 13]

Thromboplastin prepared from fresh rabbit lung was used. The established normal standard for 12.5 per cent (venous) plasma was 39.5 seconds (Standard deviation = ±2.5). All estimations were done in duplicate.

The specimens of venous blood were obtained in the usual manner of venipuncture. The arterial blood samples were taken from the radial artery. The cutaneous area of puncture was first anesthetized with 1 per cent novocain.

---

*From the Department of Medicine, New York University, and the Third (New York University) Division, Goldwater Memorial Hospital, Welfare Island, New York.

Received for publication, June 24, 1943.

Plasma was obtained by the addition of 4.5 c.c. of blood to 0.5 c.c. 1/10 molar sodium oxalate and centrifugation.

Results.—More than 100 estimations of the prothrombin time of arterial and venous plasma obtained from the 26 individuals were made. In three patients serial estimations were made daily for one week. In every instance the difference between the arterial and venous plasma prothrombin time was found to be within the limits of statistical variation. In three cases the differences were on the first examination slightly in excess of these limits. Repetition of the determinations on subsequent days, however, revealed no significant difference between the respective arterial and venous plasma prothrombin time.

Discussion.—In normal individuals the prothrombin time of arterial blood was a trifle greater than that of venous blood. The magnitude of the difference was in almost every instance less than three seconds and hence within normal variation and consequently to be considered as statistically not significant.

The arterial and venous plasma prothrombin time in four cases of Laennec's cirrhosis, although moderately or markedly prolonged,* were almost identical in each instance.

Prothrombinopenia, whether induced by agents such as Dicumarol,[2, 11] salicylate[12, 13] or sulfanyl compounds,[15, 16] or occurring spontaneously as a result of chronic debility (nutritional [vitamin K?] deficiency), does not alter the relationship which appears normally to exist between the prothrombin time of arterial and venous plasma.

It is apparent, therefore, that in man (as in dogs[4]) no significant difference between arterial and venous plasma prothrombin time is demonstrable. Should such a variation arise it would be distinctly abnormal. It might conceivably occur as a result of an unusual interchange within the pulmonary system or at the peripheral capillaries.

It is here established that for practical purposes arterial or venous blood may be used interchangeably for estimation of the prothrombin time.

Summary.—The greater sensitivity of diluted plasma as compared with whole plasma for estimation of prothrombin time is emphasized.

The prothrombin time of peripheral arterial plasma is generally a trifle in excess of that of venous plasma. The difference, however, is within the range of statistical variation and consequently not significant.

The findings herein recorded indicate that when prothrombinopenia is induced by agents such as Dicumarol, salicylate, or sulfanyl compounds, the arterial and venous plasmas are equally affected. This is also true of prothrombinopenia arising spontaneously in consequence of debilitating disease. Hence, the normally existing relationship between arterial and venous plasma is unaffected by the development of prothrombinopenia.

Arterial and venous blood may be used interchangeably for estimation of prothrombin time.

The work was conducted in part at the Home of the Daughters of Israel, New York City, through the generous cooperation of Dr. Julius Raab.

The author wishes to thank the following physicians for their assistance in obtaining blood samples. Dr. Robert C. Murphy, Jr. (St. Lukes Hospital); Dr. Sylvan M. Stillman (Bellevue Hospital).

Dicumarol was supplied by Dr. R. K. Richards of Abbott Laboratories, North Chicago, Ill.

Miss Frances Kaufman gave technical assistance.

---

*Moderate prolongation: between 1½ and twice normal. Marked prolongation: greater than twice normal.[14]

LABORATORY METHODS

GENERAL

USE OF TERTIARY BUTYL ALCOHOL IN BACTERIOLOGIC STAINING PROCEDURES*

Parker R. Beamer, Ph.D., M.D., and Robert E. Stowell, M.D., St. Louis, Mo.

Bacteriologists and clinical pathologists may desire satisfactory substitutes for certain reagents which are becoming increasingly expensive and difficult to obtain.

Tertiary butyl alcohol was introduced into microtechnical procedures by Johansen,[1] who subsequently developed methods for its use as a dehydrating agent in plant microtechnique.[2-4] Stowell[5, 6] found this reagent satisfactory for dehydration of a large variety of mammalian tissues and recommended its use in place of ethyl alcohol to help conserve reagents which are vital to our war industries.[7]

Various solvents such as methyl, ethyl, and isopropyl alcohols and acetone have been used as decolorizing agents in making Gram stains of bacterial films. In the present study over five hundred preparations of pure cultures, mixed suspensions, unknown organisms isolated at autopsy, urethral pus, and tuberculous sputum were stained. Except for sputum, the films were stained by the routine Gram staining procedure used in this laboratory and also by a procedure substituting tertiary butyl alcohol for ethyl alcohol as a stain solvent and decolorizing reagent; likewise, in the destaining of nonacid-fast organisms in sputum, tertiary butyl alcohol was substituted for ethyl alcohol.

EXPERIMENTAL

Preparation of Solutions.—The primary Gram stain was prepared by dissolving 2 Gm. of crystal violet (or gentian violet, Coleman-Bell) in 20 c.c. of tertiary butyl alcohol. This was then mixed with 80 c.c. of a 1 per cent aqueous solution of ammonium oxalate and filtered. Gram's iodine solution (0.33 per cent iodine, 0.67 per cent potassium iodide in distilled water with a small lump of calcium carbonate added to stabilize the solution) was used as the mordant. Ethyl alcohol (95 per cent) or tertiary butyl alcohol was used to destain the Gram negative organisms. The counterstain was a 2.5 per cent aqueous solution of safranine.

Carbolfuchsin solution employed in a modified Ziehl-Neelsen technique was prepared by dissolving 0.3 Gm. of basic fuchsin in 10 c.c. of tertiary butyl alco-

*From the Department of Pathology, Washington University School of Medicine, and The Barnard Free Skin and Cancer Hospital, St. Louis, Missouri.

Received for publication, November 14, 1942.

hol and mixing this with 90 c.c. of a 5 per cent aqueous solution of phenol. A 5 per cent solution of nitric acid in tertiary butyl alcohol or in ethyl alcohol (95 per cent) was used for decolorizing.

Procedures and Results.—In order to determine the proper time relations when tertiary butyl alcohol was used as a decolorizing agent, *Staphylococcus aureus* and *Escherichia coli* were selected as test organisms. Several bacterial films made in the usual manner were stained by the modification of Gram's procedure used satisfactorily in this laboratory for routine work (crystal violet, iodine solution, 95 per cent ethyl alcohol, and safranine applied in order, ten to fifteen seconds each, followed by washing in tap water). Similar films were prepared and stained in order to test the action of various concentrations of tertiary butyl alcohol as a destaining agent. Dilutions of tertiary butyl alcohol were prepared, and each was used in several series of stains in which the time of application of the primary stain, the iodine solution, or the decolorizing agent was varied. For example, in one series the primary stain and iodine solution were applied for a constant time and the period of destaining was altered for individual slides. Each slide was compared with one or more stained by the routine method using ethyl alcohol. When a satisfactory time for decolorizing was determined, other series were studied in which the time of primary staining or application of iodine solution was altered. These slides, likewise, were compared with routine stains. The series were repeated with each of the aqueous dilutions of tertiary butyl alcohol. In general, the periods of time (ten to sixty seconds) during which the primary stain or the iodine solution was applied made little difference in the results.

With 10, 20, and 30 per cent solutions of tertiary butyl alcohol the results were variable and unsatisfactory. When applied as long as five minutes, 50 per cent or less of the Gram negative forms were properly decolorized. Films which were decolorized with 40, 50, or 60 per cent tertiary butyl alcohol showed better differentiation between Gram negative and positive organisms, but variable numbers of the Gram negative forms were not destained unless the tertiary butyl alcohol was applied for two minutes or longer. Under these conditions, however, the Gram positive organisms in the thinner portions of the films were slightly decolorized. This was true especially if the iodine solution had been prepared several weeks previously.

After further studies it was found that tertiary butyl alcohol in concentrations of 60, 70, 80, or 90 per cent was satisfactory for destaining. Dependent on certain factors such as thickness of the film, the time of destaining, and the stability of the iodine solution, Gram negative organisms were properly decolorized and differentiation was good. The most satisfactory results were obtained when thin bacterial films were stained in the following manner:

1. Crystal violet solution, ten seconds; wash in tap water.
2. Iodine solution, ten seconds; wash in tap water and shake slide free of water.
3. Eighty per cent tertiary butyl alcohol, sixty to ninety seconds; wash in tap water.
4. Safranine solution, ten to fifteen seconds; wash and dry.

If thin, even films were prepared, 60 per cent and 70 per cent concentrations of tertiary butyl alcohol differentiated Gram negative forms well but less satisfactorily than did the procedure outlined above. Stains prepared according to this method were compared with those made by the routine procedure (using 95 per cent ethyl alcohol as a decolorizing agent) in identifying organisms isolated from nearly one hundred patients at autopsy. During the course of these studies the following organisms were cultured and satisfactorily stained by the method outlined: *Proteus vulgaris, Serratia marcescens, Staphylococcus aureus* and *albus, Escherichia coli, Alkaligenes faecalis,* streptococci, *Actinomyces hominis,* diphtheroids, *Sarcina lutea, Neisseria catarrhalis,* unidentified sporulating rods, *Pseudomonas aeruginosa,* and two type cultures of Salmonella.

In applying this method to several smears of urethral pus from different patients with acute gonorrhea, it was observed that, except with very thin smears, the time of destaining should be extended to two or three minutes. As other workers have indicated, preparations were satisfactory when pus cells were stained well with the counterstain.

A 5 per cent solution of nitric acid in 50 to 80 per cent tertiary butyl alcohol was satisfactory for decolorizing nonacid-fast bacteria in specimens of tuberculous sputum. Excellent differentiation was obtained by the application of steaming carbolfuchsin for five minutes, followed by destaining for one to two minutes before applying the counterstain.

DISCUSSION

The procedure outlined in this study is not proposed to supplant methods now used in preparing Gram stains, but rather to suggest a method which may be employed satisfactorily in the event that reagents now in common use become too expensive or difficult to obtain. Tertiary butyl alcohol, therefore, may be of importance in bacteriologic staining procedures, since it yields satisfactory results and it is a surplus by-product in the oil industry. According to sales agents[8] of the manufacturer, the supply of tertiary butyl alcohol is plentiful, and it may be obtained without any difficulty. This has been confirmed by the War Production Board.[9] In contrast, the supply of normal and secondary butyl alcohols is limited owing to their important uses in war industries. In the United States most of the tertiary butyl alcohol is marketed as one anhydrous grade produced by one oil company. Retail prices, however, show considerable variation, some firms asking about ten times the wholesale cost. On the basis of comparative prices of 55-gallon drum lots, tertiary butyl alcohol, which is tax-free, is only slightly more expensive than the average price of 95 per cent ethyl alcohol without the added tax.

Pure tertiary butyl alcohol, $(CH_3)_3$—C—OH, although said to be three times as toxic as ethyl alcohol, should be safe for use in the laboratory if ordinary precautions are taken to avoid prolonged exposure to high concentrations of the alcoholic vapors. The compound melts at 23 to 25.6° C., and as traces of water are taken up the melting point is lowered. When the melting point is above 23° C., at least 99.4 per cent of the reagent is present. If the room temperature is below the melting point of the alcohol, the stock bottle may be left in a warm place such as the top of an oven or near a radiator. Tertiary butyl

alcohol is miscible with most reagents in common use in the laboratory, including water, ethyl alcohol, ether, xylene, benzene, and chloroform.

SUMMARY

Tertiary butyl alcohol, a readily available, reasonably priced reagent, is satisfactory as a decolorizing agent in modifications of the Gram and Ziehl-Neelsen staining procedures. Should commonly used reagents become too expensive or unobtainable, tertiary butyl alcoohl may be used in these methods.

A NEW AND RAPID STAINING METHOD FOR GRAM-POSITIVE AND GRAM-NEGATIVE ORGANISMS IN FROZEN AND PARAFFIN SECTIONS

Aram A. Krajian, Sc.D., Los Angeles, Calif.

Christian Gram[1] in 1884 devised his method for the demonstration of bacteria in tissue sections. Weigert's[2] modification of Gram's method has been useful for the demonstration of fibrin and bacteria and is still widely used, but both methods demonstrate only gram-positive organisms.

Since then, numerous attempts have been made to demonstrate both gram-positive and gram-negative organisms in paraffin sections of tissues that had been fixed in Zenker's solution or in formaldehyde solution, and methods accomplishing this purpose have been reported by MacCallum,[3] Lyon,[4] Lillie,[5] Brown and Brenn,[6] Rudnikoff and Stawsky,[7] Glynn,[8] and others.

In these modifications, the staining solutions as devised by Gram remained practically unchanged. No attempt has been made to devise a new method by the use of some other dye or chemical, and no recommendations have been made as to the applicability to frozen sections.

The solutions used by Gram and used in the modifications of his method are: gentian violet, methyl violet, and crystal violet, as gram-positive stains; Gram's solution and compound solution of iodine, U.S.P. (Lugol's solution), as

Received for publication, November 22, 1942.

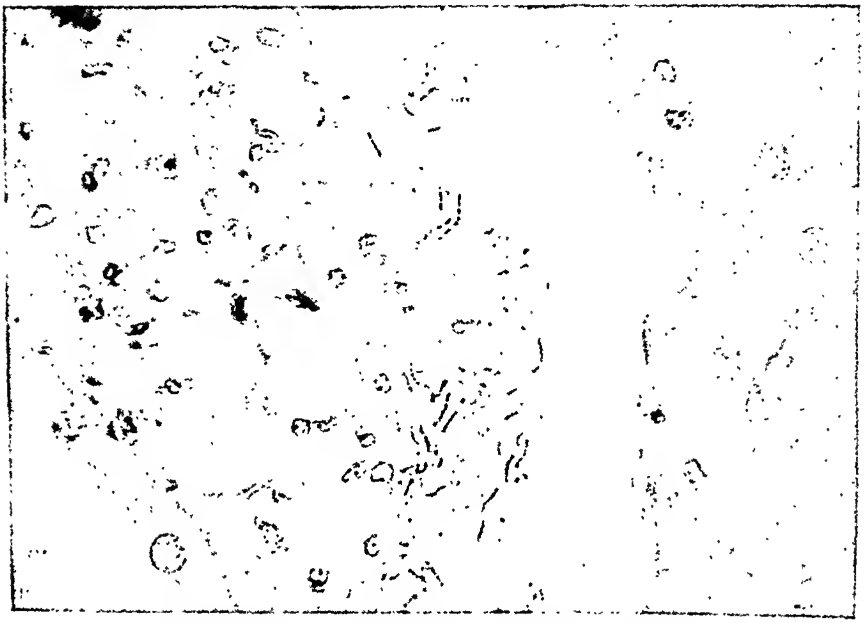

Fig. 1.—Streptococcus in kidney, stained blue; ×1620.

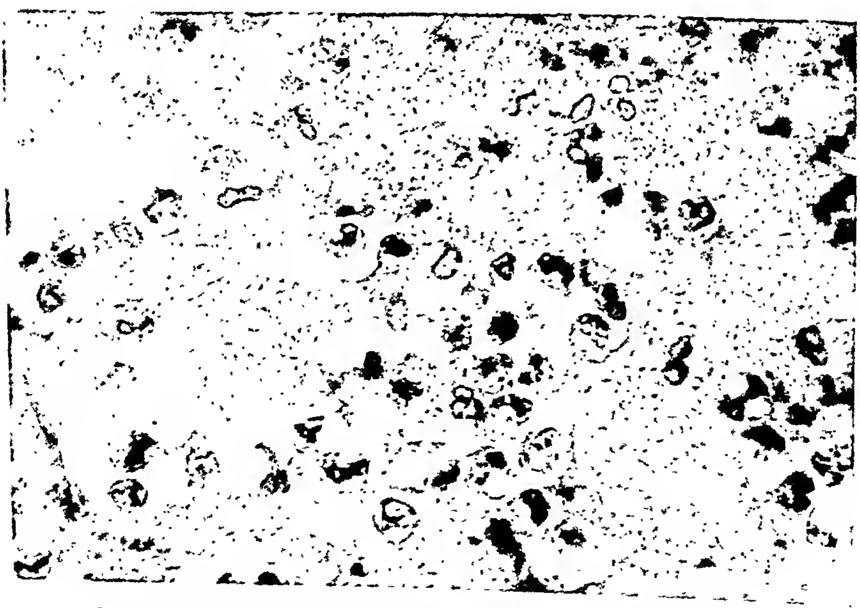

Fig. 2.—Friedländer's bacilli in pneumonia, stained red; ×1620.

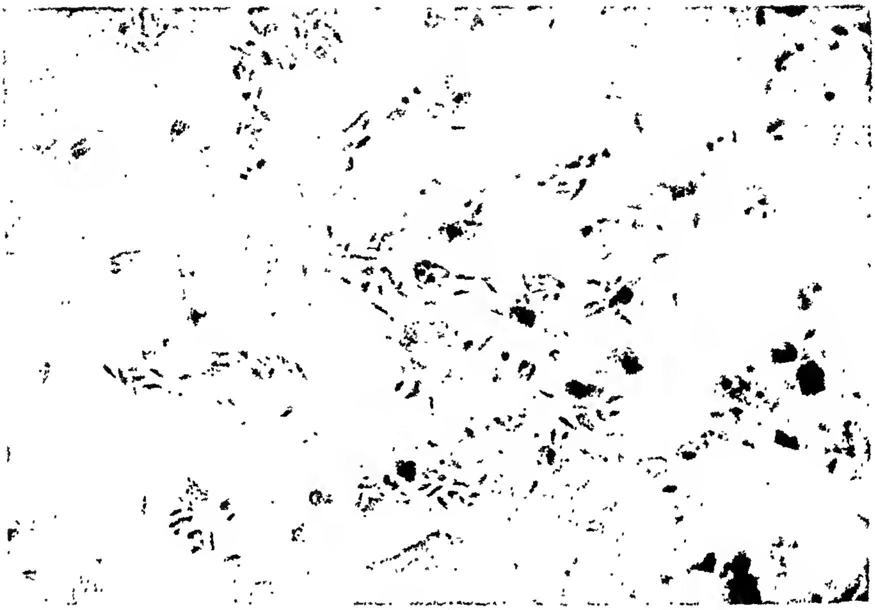

Fig. 3.—Sporotrichum in testicle, stained blue; ×1620.

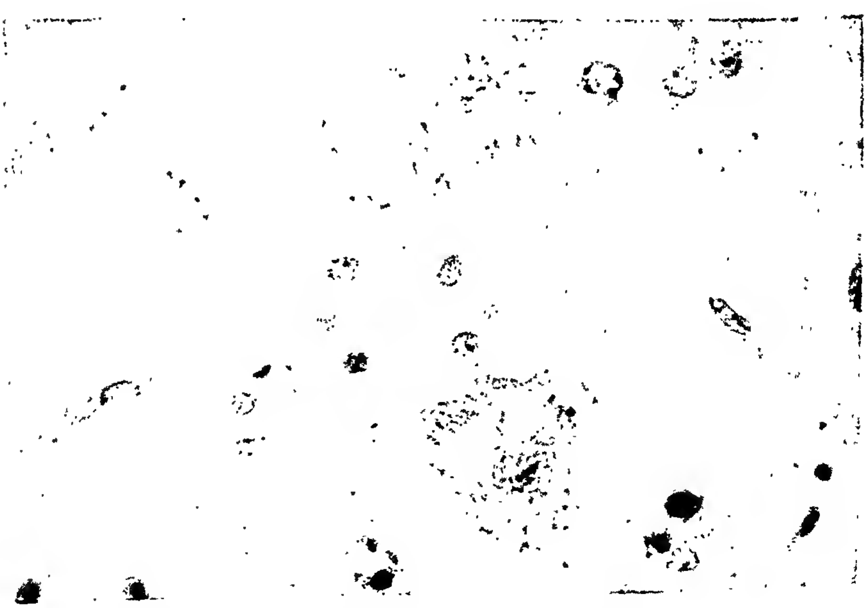

Fig. 4.—Colon bacilli in kidney tubules, stained red; ×1620.

differentiators; rosaniline hydrochloride, basic fuchsin, dilute carbolfuchsin, and safranine as gram-negative stains; and acetone, alcohol, ether, and aniline oil-xylene as decolorizers.

The need for rapid diagnosis led me to investigate the usefulness of a different dye and different solutions. A new and simple method was devised which is easily applied to frozen and paraffin sections of formaldehyde fixed tissue and which gives satisfactory simultaneous differential staining of gram-positive and gram-negative organisms. For example, four different sections (frozen or paraffin) mounted on the same slide, one of each of a kidney containing monilia, a lung with Friedländer's bacilli, a testicle containing sporotrichum, and a kidney with colon bacilli, were stained, with successful differentiation of the organisms by the method described. The technique has also been used on tissues containing streptococci, Welch bacilli, influenza bacilli, actinomyces, meningococci, gonococci, diphtheria bacilli, and Negri bodies. Similar results are obtained in another method recently described by me,[9] but the time and material required has been greatly decreased in the present technique.

In this new method, the solutions used are: methylene blue as a gram-positive stain, fuchsin-creosote as a gram-negative stain, creosote-xylene as a differentiator.

THE FROZEN SECTION METHOD

1. Prepare mounted frozen sections at 7 to 10 microns in the usual manner.
2. Stain for three minutes with alkaline methylene blue (Loeffler's).
3. Wash in tap water and dehydrate rapidly with three applications of anhydrous isopropanol or absolute ethyl alcohol.
4. Differentiate rapidly with creosote-xylene (1 part creosote plus 2 parts xylene), agitating slide constantly for five to ten seconds.
5. Pour off and apply creosote-fuchsin (2.5 c.c. of a 6 per cent alcoholic basic fuchsin added to 50 c.c. of creosote-xylene), agitating slide about 15 to 20 times, changing the solution once.
6. Blot and apply creosote-xylene 2 or 3 times, agitating the slide constantly for even decolorization or until most of the excess red color leaves the section.
7. Blot, clear for two minutes in xylene and mount in gum dammar.

FOR PARAFFIN SECTIONS

Deparaffinize section with two applications of xylene and two applications of absolute alcohol or isopropanol; bring down to tap water and then proceed with the method described.

With the use of this method, nuclei are red, gram-positive organisms blue, gram-negative organisms red, devitalized gram-positive organisms red, monilias and actinomyces blue, Negri bodies bright red with bluish chromatin bodies, and fibrin sometimes blue and sometimes red.

All the staining solutions are stable.

SUMMARY

A new, simple, and rapid method for the demonstration of gram-positive and gram-negative organisms in frozen and paraffin sections of formaldehyde fixed tissues is presented. It has the particular advantage of demonstrating the

devitalized forms of gram-positive organisms. The staining solutions used are: methylene blue, fuchsin-creosote, creosote-xylene.

LITMUS PAPER DISPENSER*

E. E. Beohm, A.B., Philippi, W. Va.

IN USING litmus paper to test the acidity of urine the usual method of taking a strip from a vial and tearing off a piece tends to be wasteful of paper and is otherwise unsatisfactory.

Fig. 1.

The use of vials filled with cut squares to be removed by the fingers likewise has its disadvantages in that the fingers must be dry; else some of the paper may be ruined, etc.

*From The Myers Clinic Laboratory, Philippi, W. Va.
Received for publication, November 22, 1942.

To eliminate these difficulties we have devised a litmus paper dispenser, which has proved to be a distinct aid in our laboratory. A Petri dish is used to hold squares of litmus paper (best cut from one strip at a time so that they will not tend to stick together). The dish is divided into two compartments for red and blue paper by a piece of 7 mm. glass rod, cemented to the glass by household cement. A pair of tweezers is used to pick up the squares of paper.

Fig. 1 is a photograph of the dispenser.

THE COMBINING POWER OF STAPHYLOCOCCUS TOXOID AS AN IDENTITY TEST*

LYON P. STREAN, M.Sc., Ph.D., D.D.S., MONTREAL, CANADA

MANY favorable reports on the use of staphylococcus toxoid in the treatment of localized staphylococcal infections have now appeared (Dolman,[1] Connor and McKie,[2] Whitby,[3] and Murray[4]). The control of innocuity and antigenic potency of this product is governed adequately by the regulations of the National Institute of Health relating to staphylococcus toxoid. The same regulations also require identity tests, where possible, for all biologicals.

It is the purpose of this communication to outline a procedure which has proved satisfactory over a period of several years as an identity test for staphylococcus toxoid.

The method employed for identifying staphylococcus toxoid consists essentially of its ability to combine with staphylococcus antitoxin in the presence of rabbit red blood corpuscles as an indicator. It is necessary to have staphylococcus alpha toxin of suitable hemolytic power for rabbit red cells.

PROCEDURE

The first step in the procedure is to determine the lethal dose of the toxin, and this is done in the following manner. Serial dilutions of toxin are made in ten serologic tubes so that Tube 1 contains 1 c.c. of a 1:10 dilution and Tube 10 contains 1 c.c. of a 1:100 dilution. Standard staphylococcus alpha antitoxin is added to the tubes in constant quantity so that each c.c. contains 1 International Unit. One c.c. of 4 per cent washed rabbit erythrocytes is added to each tube and the final volume is made up to 4 c.c. with physiologic saline. The tubes are incubated in a water bath for sixty minutes at 37° C. A sample titration is found in Table I.

The 50 per cent end point is observed in Tube 7, which contains staphylococcus toxin in a dilution of 1:25, and the lethal dose is considered as 0.04 c.c.

In order to establish the identity of the unknown material (staphylococcus toxoid?), the titration is altered somewhat so that the material under test is con-

*From the Research and Biological Laboratories, Ayerst, McKenna and Harrison, Ltd., Montreal.

Received for publication, December 12, 1942.

tained in the hemolytic system. One c.c. of the material may be diluted 1:2 or 1:4 and is added in constant quantity. A sample titration is found on Table II.

Thus it is observed that by the addition of the unknown material to the hemolytic system, the 50 per cent end point was moved from Tube 7 to Tube 9, proving that combination has taken place between the unknown material and staphylococcus antitoxin. The only variable between the two hemolytic systems being the unknown in the second titration; therefore, the conclusion can justifiably be drawn that the unknown material must be staphylococcus toxoid.

Results per cent hemolysis	100	100	100	100	100	90	50	25	0	0

TABLE II

TITRATION TO DETERMINE COMBINING POWER OF MATERIAL (STAPHYLOCOCCUS TOXOID) UNDER TEST

TUBE NO.	1 c.c.	2 c.c.	3 c.c.	4 c.c.	5 c.c.	6 c.c.	7 c.c.	8 c.c.	9 c.c.	10 c.c.
Unknown 1:4 Dil.	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Staphylococcus Toxin 1:10 Dil.	1.0	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1
Saline	-	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
Staphylococcus Antitoxin 1 I.U.	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Rabbit red blood cells 4 per cent	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Results per cent Hemolysis	100	100	100	100	100	100	100	90	50	0

CONCLUSIONS

The procedure described for the identification of staphylococcus toxoid is simple and efficient. Since the lethal dose of the staphylococcus toxin must be determined as one of the mandatory tests in the establishment of the potency of the material, no added substances are necessary in the performance of the identity test save that of the material under test.

RAPID BIOLOGICAL METHOD FOR THE APPROXIMATE DETERMINATION OF ACETYLCHOLINE AND POTASSIUM IN BODY FLUIDS*

CLARA TORDA, PH.D., M.D., NEW YORK, N. Y.

THE acetylcholine content of body fluids is usually determined by biological methods. Since potassium affects the result and its content in the body fluids varies greatly, it is necessary to differentiate its effects from those of acetylcholine. The differentiation is possible by the combined application of two or more of the methods in common use. Some of the more common methods are:

(1) Chemical determination of the acetylcholine content.
(2) Chemical determination of the potassium content.
(3) Comparison of the effect of various dilutions of the body fluid on a sensitive tissue.
(4) Precipitation of potassium by permutit (Lánczos.[1]).
(5) Comparison of the effect of the unknown body fluid on the biological test objects before and after eserinization.
(6) Comparison of the effect of the unknown body fluid on the biological test objects before and after atropinization.

Such a combination, while giving reliable results, requires much time.

This paper describes a rapid method for the approximate determination of acetylcholine and potassium. The effects of the procedure are fully reversible, making a check possible. The method is based on the property of calcium to counteract the effect of potassium. The rectus abdominis muscle of the frog was used as the test object, as suggested by Riesser,[2] and Chang and Gaddum.[3]

METHODS

The rectus abdominis of the frog was excised and suspended in a muscle chamber containing 20 c.c. of Ringer's solution (114 mM NaCl, 2 mM KCl, and 1.8 mM $CaCl_2$). After one hour the Ringer's solution was replaced for thirty seconds by a test solution containing substances causing contraction of the muscle. The height of contraction was registered by an isotonic lever on a kymograph. The muscle was then washed for ten minutes in Ringer's solution and the procedure repeated until three successive exposures to a test solution gave similar responses. At this point the counterbalance on the lever was adjusted so that the height of the reading on the kymograph was the same in the various experiments. Then the muscle was exposed to a series of test solutions for thirty seconds and washed with Ringer's solution for ten minutes.

In order to eserinize the muscle it was immersed for thirty minutes in a 0.0004 per cent physostigmine salicylate solution. Between exposures to the

*From the Department of Pharmacology, Cornell University Medical College, New York.
Received for publication, December 21, 1942.

various test solutions the eserinized muscle was washed first with Ringer's solution for five minutes and then with physostigmine for five minutes.

The test solutions used were:

(1) Acetylcholine solution containing 0.1 to 0.01 mg. per 100 c.c. with uneserinized muscles and 0.01 to 0.001 mg. per 100 c.c. with eserinized muscles.
(2) 20 to 60 mM potassium.
(3) Both acetylcholine and potassium.

Calcium was present in the various solutions in concentrations of from 0 to 180 mM. The solutions were rendered isotonic with Ringer's solution by the addition of NaCl. The pH was corrected to 7 when necessary by the addition of acid or basic phosphate. Air was bubbled through the solutions in the muscle chamber during the experiments.

The results were tabulated in millimeters of excursion of the lever as measured from the records.

TABLE I

ACETYLCHOLINE AND POTASSIUM CONTRACTIONS OF THE RECTUS ABDOMINIS MUSCLE IN RELATION TO THE CALCIUM CONCENTRATION

SUBSTANCE	NO. OF EXPTS.	AVERAGE CONTRACTION IN PER CENT OF THAT OBTAINED IN RINGER'S SOLUTION (Ca 1.8 mM) FOLLOWED BY STANDARD ERROR OF MEAN				
		18 mM $CaCl_2$	36 mM $CaCl_2$	54 mM $CaCl_2$	90 mM $CaCl_2$	180 mM $CaCl_2$
Acetylcholine*	25	90 ± 1.0	85 ± 0.9		80 ± 1.1	
20 mM Potassium	25	35 ± 0.9	16 ± 0.5		11 ± 1.1	
40 mM Potassium	25	55 ± 0.9	35 ± 0.9		11 ± 1.0	4 ± 0.7
60 mM Potassium	10			36 ± 1.1	18 ± 1.0	5 ± 1.0
Acetylcholine and 20 mM Potassium	10	65 ± 1.0			56 ± 1.0	
Acetylcholine and 40 mM Potassium	10		65 ± 1.0		55 ± 1.0	

*For concentration of acetylcholine see text.

RESULTS

The Effect of Acetylcholine in the Presence of Various Concentrations of Calcium.—The results, summarized in Table I and Fig. 1, show that an increase of the calcium content of the acetylcholine solution from 1.8 to 18 mM decreased the height of contraction caused by acetylcholine by about 10 per cent; and an increase of the calcium content to 90 mM decreased the height of contraction by about 20 per cent. Thus, varying the concentrations of calcium in the test solution had but little effect on the height of contraction caused by acetylcholine. This was true with both eserinized and uneserinized muscle, the only difference being in the absolute concentration of acetylcholine necessary to produce the contraction.

The Effect of Potassium in the Presence of Various Concentrations of Calcium.—The results are given in Table I and Fig. 1. They are expressed as a percentage of the response to solutions containing respectively 20, 40, and 60 mM potassium in the otherwise standard Ringer's solution (Ca, 1.8 mM). The

effectiveness of all these potassium solutions fell off rapidly as the calcium concentration was increased. At the higher potassium concentrations slightly more calcium was required to produce a given reduction in the response, but for all three concentrations 180 mM calcium caused a reduction in the average response to 5 per cent or less of the control value.

The Effect of Acetylcholine Plus Potassium in the Presence of Various Concentrations of Calcium.—The contracting effect of a solution containing acetylcholine and potassium is greater than one containing acetylcholine or potassium alone.

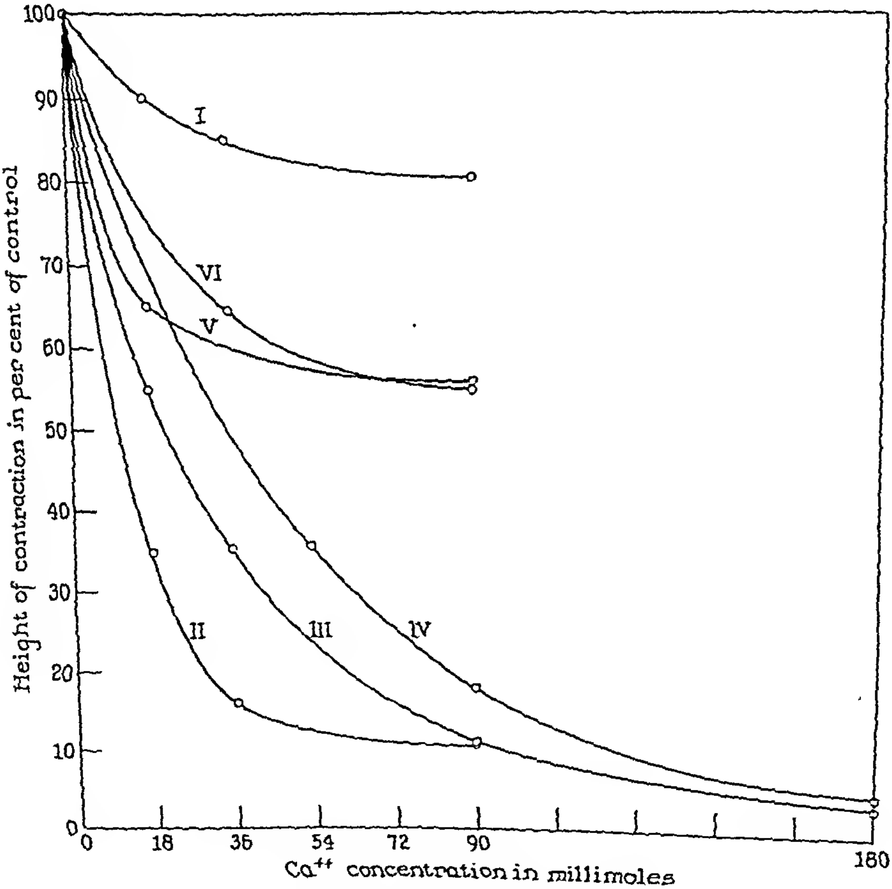

Fig. 1.—Influence of calcium on the contraction of the rectus abdominis muscle caused by acetylcholine and potassium. Values are expressed in percentage of the control response with muscle in Ringer's solution (1.8 mM Ca). The height of contraction in per cent is plotted against the calcium concentration in millimols. I, Acetylcholine (for concentration see text). *II*, 20 mM Potassium. *III*, 40 mM Potassium. *IV*, 60 mM Potassium. V, Acetylcholine and 20 mM Potassium. *VI*, Acetylcholine and 40 mM Potassium.

In the first series of experiments the muscle response to a solution containing 0.1 to 0.01 mg. acetylcholine per 100 c.c., 20 mM potassium, and 1.8 mM calcium was recorded. An increase in the calcium content to 18 mM decreased the height of contraction by about 35 per cent, and an increase of the calcium concentration to 90 mM caused a 44 per cent decrease. In the second series of experiments the muscle was exposed to a solution containing acetylcholine (0.1 to 0.01 mg. per 100 c.c.), 40 mM potassium and 1.8 mM calcium. An increase of the calcium con-

centration to 36 mM decreased the height of contraction by 35 per cent, and an increase of the calcium concentration to 90 mM caused a 44 per cent decrease. This effect was observed with both eserinized and uneserinized muscle, the only difference being the concentration of acetylcholine required to produce the contraction.

A series of experiments paralleling the experiments described above in which proteins were added to the test solution have been carried out with results similar to those summarized in Table I and Fig. 1.

The technique described may be used for an approximate determination of the acetylcholine and potassium content of an unknown solution by the following procedure: First, the eserinized rectus abdominis of the frog is immersed in the unknown solution, the height of contraction registered. Then to an aliquot, 90 mM calcium is added and the contracting effect of this solution is measured. If the increase in the concentration of calcium does not modify significantly the height of contraction, it may be assumed that the original solution contained acetylcholine and little or no potassium. If on the other hand the height of contraction is decreased by 80 or 90 per cent, the solution may be assumed to contain potassium but no acetylcholine. If an intermediate result is obtained, it may be assumed that both potassium and acetylcholine are present in the unknown solution.

The method can be used for quantitative estimation of the acetylcholine or potassium content of an unknown solution:

If the solution contains acetylcholine alone, the acetylcholine content can be estimated by comparing the height of contraction of the muscle immersed in the unknown solution with the height of contractions caused by known solutions.

If the solution contains potassium without acetylcholine, a determination of the amount of potassium is possible by varying the calcium concentration of the solution. If the addition of 36 mM calcium decreased the height of contraction by about 80 per cent, it may be assumed that the unknown solution contains about 20 mM potassium. If the decrease is 65 per cent, the original solution probably contains 40 mM potassium, and similarly if the decrease is 50 per cent, the solution probably contains 60 mM potassium.

With a solution that contains both acetylcholine and potassium a similar procedure can be carried out. For example, if the addition of 18 mM calcium to the unknown solution results in a 35 per cent decrease in the height of contraction, it may be assumed that the solution contained about 20 mM potassium. Similarly if the addition of 36 mM calcium to the unknown solution results in a 35 per cent decrease of the height of contraction, the solution contained about 40 mM potassium. After estimation of the concentration of potassium of the unknown fluid, the acetylcholine content can be estimated by the usual method indicated above. The height of contraction caused by the unknown solution must be compared with the height of contraction produced by known solutions of acetylcholine dissolved in the same concentration of potassium as the unknown solution.

The potassium content of the unknown solution may also be determined by plotting the height of contraction of the rectus abdominis, as expressed in percentage of the first contraction, against the increase of the calcium content of

the fluid. By a gradual increase of the calcium content from zero to a high concentration, the curve obtained is a hyperbola. As the ratio of the K/Ca content of the solution decreases towards unity, the curve falls sharply. As the ratio becomes less than unity, the curve starts to level out and approximate asymptotically the base line.

The body fluids contain buffers, most of which form insoluble salts with calcium; therefore, a correction must be made for the amount of calcium precipitated. This can be accomplished by adding calcium in small amounts until no further precipitate is formed. Any further amounts of calcium added remain for the most part in solution and are available to counteract the effect of potassium. The pH of all solutions must be corrected to the same level, since the height of contraction varies with the pH.

Immersion of the muscle for a few minutes in Ringer's solution is sufficient to reverse the effect of a few minutes' immersion in calcium.

The method was tested for urine. Acetylcholine (0.1 to 0.001 mg. per 100 c.c.), potassium (20 to 50 mM) or both acetylcholine and potassium were dissolved in urine and the added amount determined. The difference between the amount of substances added and that estimated by the muscle test was less than ±15 per cent.

DISCUSSION

This paper offers a method of determining the approximate content of acetylcholine and/or potassium in an unknown solution based on the effect of calcium in counteracting the effect of potassium on the rectus abdominis muscle.

The method is only approximate because of the following sources of error:

(1) The calcium-potassium antagonism on muscle contraction is not absolute.
(2) The original calcium ion content of the unknown solution is not known.
(3) It is difficult to estimate the exact amount of ionized calcium in case some of the added calcium precipitates.
(4) The unknown fluid might contain other substances which cause muscle contraction and which are more or less influenced by calcium.

The above studies prove that the effect of acetylcholine as a contraction-producing agent is somewhat modified by an increase in the concentration of calcium in the surrounding fluid. They also prove that the contraction of the muscle is due not to an excess of potassium per se, but to an increase of the K/Ca ratio. The calcium-potassium antagonism is not a simple relationship, since exceedingly large amounts of calcium are necessary to counteract completely the effect of potassium.

SUMMARY

(1) A biologic method for the rapid estimation of acetylcholine and/or potassium content of body fluids is offered. The method is based on the antagonism between calcium and potassium on the contraction of the rectus abdominis muscle of the frog.

(2) The contracting effect of acetylcholine on the muscle is but slightly influenced by a large excess of calcium.

(3) The contraction caused by potassium can be prevented almost completely by a large amount of calcium.

A STUDY OF PRESERVED COMPLEMENT*

PAUL FUGAZZOTTO, M.S., GRAND RAPIDS, MICH.

THE most uncertain factor in complement fixation tests has always been the complement itself, since it is practically impossible to predict how long any particular lot of freshly drawn guinea pig serum will retain its potency. Especially distressing is the instability of complement diluted for tests; and it is perhaps because of this instability that some attempts at complement fixation have met with little success.

During recent years, however, several workers have attempted to reduce the factor of uncertainty by various methods of preservation. Ginsburg and Kalinin[1] reported satisfactory preservation of guinea pig complement for three to four months by addition of 100 mg. sodium chloride and 40 mg. boric acid per c.c. of serum. The method used in the present study is based on the one described by these authors and differs mainly in that 80 mg. instead of 100 mg. of sodium chloride were used.

PREPARATION OF PRESERVED COMPLEMENT

For each pool of complement serum, 8 to 10 c.c. of blood were drawn by cardiac puncture from each of four or more healthy adult guinea pigs, under ether anesthesia. The blood was collected separately in sterile Petri plates, left at room temperature for an hour, and in the cold room four to twenty hours. (Petri plates were used to allow greater surface for evaporation of the ether with which the blood becomes saturated during anesthesia.) The clots were carefully removed, avoiding hemolysis. The clear sera were obtained by the minimum amount of centrifugation and placed immediately in the cold room. Within twenty-four hours after bleeding the animals, a portion of each serum was removed for titration according to the technique given later. In this titration, unless there was complete hemolysis of one unit of sensitized sheep cells in the presence of less than 0.05 c.c. of the 1:15 diluted complement, the latter was not included in the pool.

The satisfactory sera were pooled in a large sterile test tube fitted with a cotton plug. After the volume had been determined, 80 mg. of sodium chloride

*From the Michigan Department of Health Laboratories, Western Michigan Division.
Received for publication, January 28, 1943.

and an excess (40 mg.) of pulverized boric acid were added per c.c. of serum. If it were not possible to titrate the sera within twenty-four hours, proportionate amounts of the salts were added to the individual sera; the mixtures were shaken till it was certain that all the sodium chloride had dissolved; and the titrations were done later. Since boric acid dissolves very slowly, the mixture was agitated about three times daily for two days to insure maximum solubility. When the odor of ether was no longer detectable in the serum, the cotton plug was replaced by a cork stopper to prevent further evaporation.

PREPARATION OF THE REAGENTS FOR COMPLEMENT TITRATIONS

Washed Sheep Blood Cells.—The cells of freshly drawn sheep blood were washed four times in large volumes of physiologic salt solution, and a 5 per cent suspension was made in saline.

Sensitized Sheep Cells.—The sheep cells were sensitized by mixing the required volume quickly and thoroughly with an equal volume of amboceptor diluted according to titer. The suspension was again agitated every five minutes for fifteen minutes, at which time it was considered ready for use and was discarded after one and one-half hours. Of this suspension 0.2 c.c. were used as one unit.

Titration of Amboceptor.—The amboceptor titer was determined as the highest dilution of amboceptor to the nearest 100, producing complete hemolysis of the cells in the presence of 0.05 c.c. of 1:15 diluted complement.

Because any slight error in the preparation of dilutions might result in amboceptor of varying potency and because the blood cells of different sheep vary somewhat in fragility, care was taken in so far as possible to standardize these two reagents, thereby leaving the complement as the only significant variable thoroughout the period of the experiments.

Complement.—Throughout the entire period of this work the complement sera were used at a dilution of 1:15. Dilutions of unpreserved complement were made with physiologic saline. Preserved complement was first made isotonic to normal serum by diluting it 1:10 with distilled water, and then made up to 1:15 with physiologic saline.

TECHNIQUE OF COMPLEMENT TITRATIONS

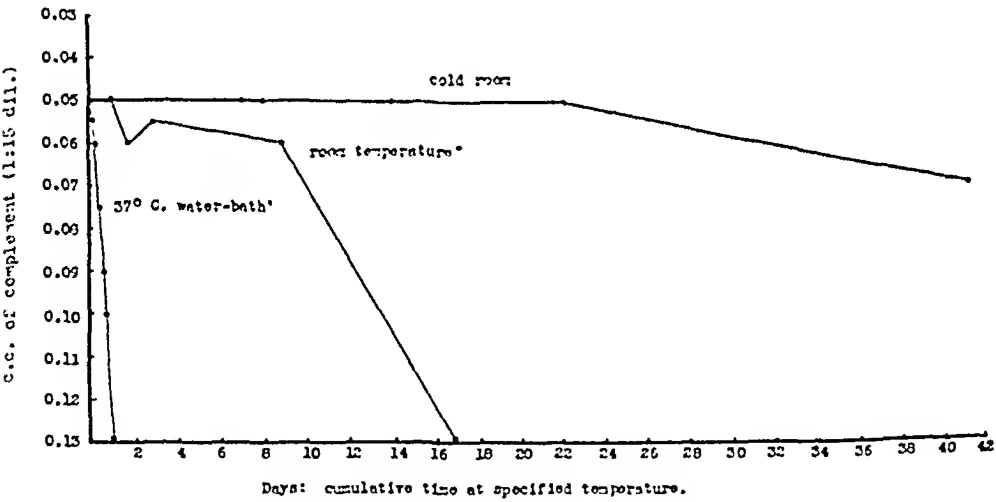
A series of several tubes was set up for each specimen of complement, and various amounts of the diluted complement were pipetted to the bottom of the tubes. To each tube was added 1 unit of sensitized sheep cell suspension. As each rack of tests was completed, it was shaken thoroughly, and placed immediately in a water bath at 37° C. for fifteen minutes. The titer recorded was the smallest volume of diluted complement, to the nearest 0.005 c.c., necessary for complete hemolysis of the sensitized sheep cells, as indicated by simple inspection.

EFFECT OF AGE AND TEMPERATURE ON THE STABILITY OF PRESERVED COMPLEMENT

At varying intervals over a period of sixteen months, complement titrations were made on 29 pooled guinea pig sera of varying ages, accumulated during this time and stored continuously in the cold room at 5° to 8° C.

One of these sera, already two and one-half months in storage, was selected to determine the effect of intermittent exposure to higher temperatures. This complement was divided into three portions, the first of which was kept continuously in the cold room. The second and third portions were also stored in the cold room when not in use; but at some arbitrarily set time before titration, the second portion was transferred to room temperature (25° to 32° C.), and the third to a 37° C. water bath. Then samples of each portion were diluted 1:15 for titrations.

Results.—In considering analysis of Graph I, it must be remembered that the complement used was already two and one-half months old at the first point plotted. The "cold room" curve, which followed a course similar to those obtained for all the pooled sera tested, continued a straight line for twenty-two days more. No test was made between the twenty-second and forty-first days, but tests with other sera indicated that the curve would have continued a straight line to the thirtieth or thirty-fifth day. Hence, preserved complement kept in the cold room would retain its activity practically constant for three to four months.



Graph 1.—Effect of temperature on stability of undiluted preserved complement indicated by c.c. of 1:15 dilution required for complete hemolysis of 1 unit of sensitized cells.

The complement was already 2.5 months old at the beginning of the experiment.

*Sera were not left continuously at the temperature specified, but stored in the cold room between test periods.

On the other hand, intermittent exposure of the complement to higher temperatures increased the rate of deterioration, as indicated by the more rapid drop in the other two curves.

EFFECT OF AGE AND TEMPERATURE ON STABILITY OF DILUTED PRESERVED COMPLEMENT

Samples of several preserved sera were diluted 1:15. The dilutions were stored in the cold room and titrated at intervals of approximately twenty-four hours for several days.

One of these diluted sera, selected to determine the effect of intermittent exposure to higher temperatures, was divided into three portions. The first of these was kept continuously in the cold room; the second and third were also

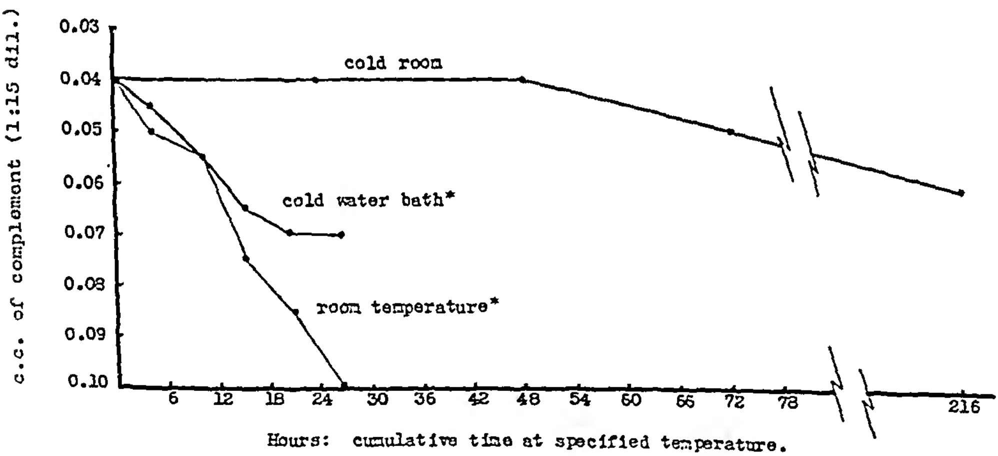
stored in the cold room when not in use. At some arbitrarily set time before titration, the second portion was transferred to a cold water bath (10° to 20° C.) and the third to room temperature (25° to 32° C.). Then samples of each were taken for titration.

Results.—The "cold room" curve in Graph II indicates that the dilution of preserved complement kept continuously in the cold room retained practically constant potency for twenty-four to forty-eight hours. This was also true of the several other diluted sera tested, some of which retained their potency still longer.

On the other hand, intermittent exposure of diluted complement to higher temperatures increased the rate of deterioration as indicated by the more rapid drop in the other two curves.

DISCUSSION

It has long been known that freshly drawn guinea pig complement can no longer be used three or four days after drawing. Furthermore, it has been the experience in the present study that a dilution of unpreserved complement demonstrated appreciable deterioration within eighteen to twenty hours even if kept at cold room temperature.



Graph II.—Effect of temperature on stability of diluted (1:15) preserved complement, indicated by number of c.c. required for complete hemolysis of 1 unit of sensitized cells.

*Sera were not left continuously at the temperature specified, but stored in the cold room between test periods.

From the data presented it seems evident that complement prepared according to the method described will remain satisfactory for a much longer period of time (three to four months) comparing favorably with the complement of Ginsburg and Kalinin. For best results, however, it is necessary to avoid exposure of the complement to temperatures above 5° to 8° C. for any considerable period of time, especially during the first twenty-four hours after obtaining the blood from the guinea pigs; that is, during the time when the salts have not yet been added. The stability of complement seemed to depend in great degree upon its plane of potency at the time the preservatives were added, an occasional pool retaining satisfactory activity for as long as six months. From this it also followed that the stability of the diluted complement depended upon the status of the pool from which it was made. A dilu-

tion of a very poor pool, one that had aged considerably or one that was poor at the very beginning, was likely to be less stable than a dilution of a good pool.

Complement preserved by freezing and drying, according to Flosdorf, Boerner, Lukens, and Ambler,[2] apparently retains its activity for periods as long as three years. The later method of Boerner, Flosdorf, and Lukens,[3] of freezing and drying after addition of sodium acetate and boric acid, also has its advantages. But the advantage of a method like the one described in this study is that it does not necessitate having special apparatus which might be too cumbersome as well as too expensive for a small laboratory. Furthermore, it is rather important to know how the frozen complement behaves after dilution for use. That is, if a dilution of this complement is only as stable as a dilution of fresh complement, it would seem from the results of the present study that there is an added advantage in the salting method.

SUMMARY

Data are presented concerning the nature of complement preserved with sodium chloride and boric acid.

Complement preserved by the method described retains its activity for three to four months. An occasional pool was found satisfactory for as long as six months.

This complement diluted to titer retained its activity almost undiminished for twenty-four to forty-eight hours when kept at 5° to 8° C.

The importance of temperature is stressed, and a cold water bath is suggested for complement (diluted or undiluted) that must be kept out of the cold room for any length of time.

CONCLUSION

The use of sodium chloride and boric acid in the manner described is a satisfactory method of preserving guinea pig complement. The use of complement so preserved should tend to increase the uniformity and dependability of the results of complement fixation tests.

AN IMPROVED FEEDER FOR GUINEA PIGS*

STEWART H. WEBSTER, PH.D., ERVIN J. LILJEGREN, AND DAVID J. ZIMMER
BETHESDA, MD.

THE frequent necessity for accurately measuring the quantity of pellet food consumed by guinea pigs on experiments led to the development of a type of feeder which has been in use in this laboratory for nearly a year. This device offers several advantages over the old style of open box. (1) Contamination of food is reduced to a minimum since the feed opening is adjustable to the size of the head. (2) Very little food is lost since the animal has to insert its head

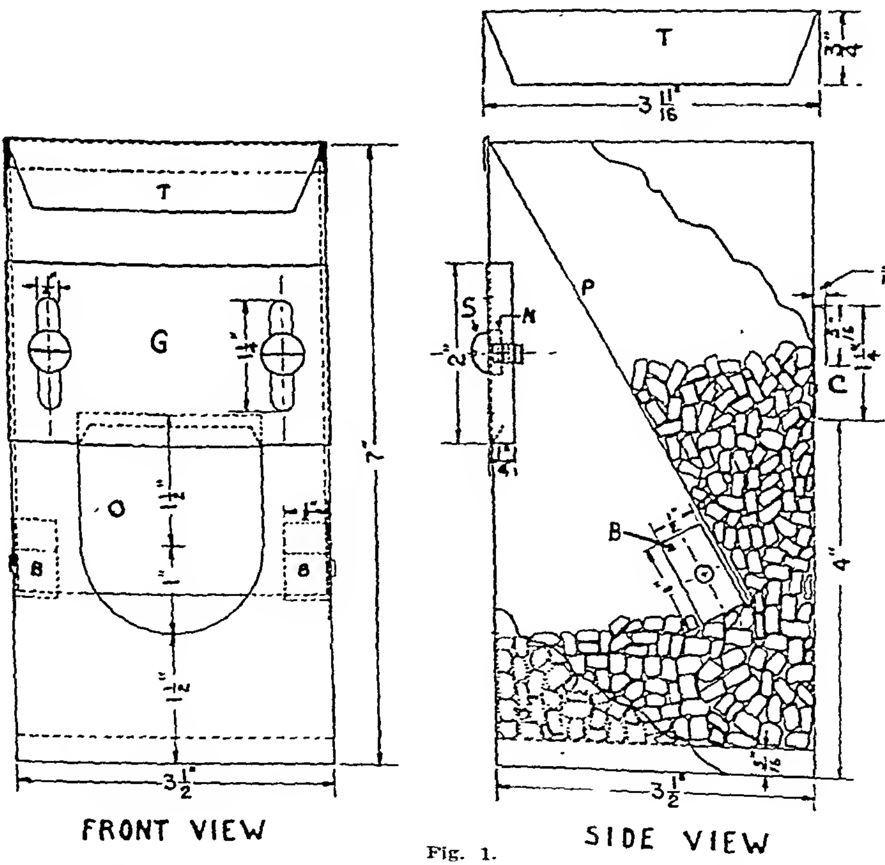

Fig. 1.

into the opening in order to secure food. (3) The capacity of the feeder, about 550 Gm. of pellet food, is sufficient for four or five animals for several days. (4) By reducing contamination and food loss the use of these feeders results in a considerable decrease of food cost. This saving should compensate for the difference in cost between these feeders and open cups.

Received for publication, January 15, 1943.

Although feeders made of wood or masonite are serviceable for a limited time, ones constructed of sheet iron are resistant to chewing by the animals. The accompanying drawing shows details and dimensions for feeders made of No. 22 gauge galvanized iron. The box, consisting of four sides with a bottom soldered in, has a smoothly formed feed opening, *O*, the size of which is regulated by the slotted gate, *G*, which is adjustable and can be locked in position by the screws, *S*, and nuts, *N*, soldered to the side. The bottom of the gate is bent upward and backward in order to eliminate any sharp edge which might cut the animal. The plate, P, 5¾ inches long by 3⅜ inches wide, keeps the feed in the hopper and is removable for cleaning. The top of this plate is bent as shown, and the lower part is held in position by the brackets, *B*, soldered and riveted to the sides. The position of these brackets governs the throat size at the bottom of the plate and consequently the flow of pellets. About ¾ inch is satisfactory for this throat width using cylindrical pellets having diameters of about $^3/_{16}$ inch and lengths ranging from ⅛ to ¼ inch. The feeder is covered with a top, *T*, the edges of which are bent inward so that friction prevents the animal from knocking it off in case it should climb on top. Finally, the clip, *C*, riveted to the back, serves to hold the feeder securely to the cage and prevents upsetting.

We wish to thank Mr. R. R. Groomes, Foreman of the Sheet Metal Shop, for suggestions in the design of this feeding device.

A RAPID METHOD FOR DETERMINING THE SULFONAMIDE DRUG OF CHOICE*

ROBERT J. ATWELL, A.B., RICHARD P. SEXTON, A.B., AND MARY A. POSTON, M.A.
DURHAM, N. C.

IN SULFONAMIDE therapy, the choice of the drug, its dosage, its effective blood level, its reactions, etc., depend both on the patient and the infecting organism. Bactericidal tests of the patient's organism with the various sulfa drugs are desirable so that the most effective one can be selected as quickly as possible. A preliminary report describing a rapid method for the determination of the drug of choice in cultures of the blood, spinal fluid, nose and throat, sputum, and wounds is presented.

MATERIALS AND METHODS

Sulfanilamide, sulfapyridine, sodium sulfapyridine,† sulfathiazole, sodium sulfathiazole, sulfadiazine, and sodium sulfadiazine were chosen for the experiments because of their adaptability to clinical use. Stock solutions of the drugs were made in beef-infused buffered broth,‡ pH 7.4,[1] using a 100 mg. per cent concentration of sulfanilamide and the sodium salts, and a 15 mg. per 100 c.c. concentration of sulfapyridine, sulfathiazole, and sulfadiazine.

*From the Department of Bacteriology, Duke University School of Medicine and Duke Hospital.

Received for publication, February 3, 1943.

†The sodium salts were used so that higher concentration of the drugs could be obtained. Since the same concentration of the drug and that of its sodium salt are not always comparable in their inhibition effects, both forms of the drug were used for these experiments. At the present time, no explanation can be given of this discrepancy, which has been noted in previous experiments.

‡See footnote on page 1621.

Buffered beef-infused (3.5 per cent) agar,* pH 7.4 was used as the stock medium for pouring plates. This was tubed in 8 c.c. amounts, to which were added varying amounts of the broth filtrates of the drugs. The final concentrations of the drugs used in the experiments were 20, 10, and 5 mg. per cent of the sodium salts; 20 and 10 mg. per cent of sulfanilamide, and 5 mg. per cent of sulfapyridine, sulfathiazole, and sulfadiazine.

BLOOD

Fifteen cubic centimeters of the patient's blood are introduced into a flask containing 4 c.c. of 2.5 per cent sodium citrate solution. One cubic centimeter of the citrated blood is added to each tube containing molten agar (cooled to 40° C.), sulfonamide solution, and broth. Control plates contain agar but no sulfonamide. If the patient is receiving chemotherapy, one plate is poured using agar containing 1 mg. per 100 c.c. para-amino-benzoic acid. The cultures are incubated at 37.5° C.

TABLE I

CHART SHOWING INHIBITION OF GROWTH OF PNEUMOCOCCUS, TYPE 27, IN CULTURE OF BLOOD AFTER EIGHTEEN HOURS' EXPOSURE TO SULFONAMIDES

SULFANILAMIDE		SULFAPYRIDINE	SODIUM SULFAPYRIDINE			SULFATHIAZOLE	SODIUM SULFATHIAZOLE			SULFADIAZINE	SODIUM SULFADIAZINE		
10*	20	5	5	10	20	5	5	10	20	5	5	10	20
0	0	++	+++	++++	++++	+++	+++	++++	++++	0	0	0	0

*Milligrams per cent.
++++ = Complete inhibition.
+++ = 75 per cent inhibition.
++ = 50 per cent inhibition.
+ = 25 per cent inhibition.

TABLE II

CHART SHOWING INHIBITION OF GROWTH OF BETA STREPTOCOCCUS IN CULTURE OF NOSE AND THROAT AFTER EIGHTEEN HOURS' EXPOSURE TO SULFONAMIDES

SULFANILAMIDE		SULFAPYRIDINE	SODIUM SULFAPYRIDINE			SULFATHIAZOLE	SODIUM SULFATHIAZOLE			SULFADIAZINE	SODIUM SULFADIAZINE		
10	20	5	5	10	20	5	5	10	20	5	5	10	20
++++	++++	++	++	+++	+++	0	0	0	0	0	0	0	0

After eighteen hours' incubation, if colonies are visible in the control plates, colony counts are made of the controls and the plates containing the drugs. Smears of the colonies are made and stained by Gram's method and the organism is identified. By this method, the drug of choice can be determined at the time the cultures are positive. (See Table I.)

NOSE AND THROAT

The swabs are placed immediately into tubes containing 10 c.c. of beef-infused broth. As much material as possible is washed from the swabs by rolling them against the inside wall of the test tube. One tenth cubic centimeter of the broth is transferred to another tube containing 10 c.c. of broth and mixed thoroughly (Tube 2). The sulfonamide, 1.5 c.c. sterile sheep's blood,

*Broth and agar containing 1 per cent bacto-peptone (Difco brand) were used instead of peptone-free media, as Gay and his co-workers[2] have shown that sulfanilamide is bacteriostatic in the presence of bacto-peptone. When media containing less than 1 per cent bacto-peptone is used, forty-eight to seventy-two hours' incubation of the cultures is required *before* colonies appear in the plates.

0.1 c.c. of the broth mixture from Tube 2, and sufficient stock broth to bring the volume up to 15 c.c. are added to each tube of molten agar (cooled to 40° C.), and after thorough mixing, plates are poured. Control plates are poured using agar without drug.

After eighteen hours' incubation, the plates are examined for organisms. If present, colony counts are made and the organisms are identified. (See Table II.)

SPINAL FLUID

The spinal fluid is centrifuged at high speed for fifteen minutes. After centrifugalization, the supernatant fluid is discarded, and a smear is made of the sediment and stained by Gram's method. A tube containing 10 c.c. of blood broth is inoculated with two to four loopfuls of the sediment, depending upon the number of organisms present in the smear, and is incubated at 37.5° C. for thirty minutes. The sulfonamide solution, 1.5 c.c. of sterile sheep's blood, 0.1 c.c. of the broth culture of the spinal fluid, and enough stock broth to bring the volume up to 15 c.c. are added to each tube of molten agar (cooled to 40° C.), and after thorough mixing, plates are poured. Control plates are poured using agar without drug. The cultures are incubated at 37.5° C.

TABLE III

CHART SHOWING INHIBITION OF GROWTH OF PNEUMOCOCCUS, TYPE 17, IN CULTURE OF SPINAL FLUID AFTER EIGHTEEN HOURS' EXPOSURE TO SULFONAMIDES

SULFANILAMIDE		SULFAPYRIDINE	SODIUM SULFAPYRIDINE			SULFATHIAZOLE	SODIUM SULFATHIAZOLE			SULFADIAZINE	SODIUM SULFADIAZINE		
10	20	5	5	10	20	5	5	10	20	5	5	10	20
+	+	++++	++++	++++	++++	++++	++++	++++	++++	+-	++	++++	++++

TABLE IV

CHART SHOWING INHIBITION OF GROWTH OF STREPTOCOCCUS HEMOLYTICUS IN CULTURE OF SPUTUM AFTER EIGHTEEN HOURS' EXPOSURE TO SULFONAMIDES

SULFANILAMIDE		SULFAPYRIDINE	SODIUM SULFAPYRIDINE			SULFATHIAZOLE	SODIUM SULFATHIAZOLE			SULFADIAZINE	SODIUM SULFADIAZINE		
10	20	5	5	10	20	5	5	10	20	5	5	10	20
++++	++++	++	++++	++++	++++	++++	0	++	++++	++	++	++	++

After eighteen hours' incubation, the plates are examined, the in vitro effectiveness of the sulfonamides is determined, and the organisms are identified. (See Table III.)

SPUTUM

A smear is made of the sputum and stained by Gram's method. One or two loopfuls of the sputum, depending upon the number of organisms present in the smear, are inoculated into a tube containing 10 c.c. of broth. One-tenth cubic centimeter of a 1:100 dilution of the sputum broth mixture is used as the inoculum, and plates are poured, as described above.

After eighteen hours' incubation, the plates are examined for organisms. If colonies are present, the bacteriostatic effect of the sulfonamides is determined and the organisms are identified. (See Table IV.)

WOUNDS

The swabs are placed immediately into a tube containing 10 c.c. of broth. As much material as possible is washed from the swabs by rolling them against

the inside of the test tube. A smear is made of the broth and stained by Gram's method. Dilutions are made according to the number of organisms in the stained smear. One-tenth cubic centimeter of the final dilution of broth is used as the inoculum, and plates are poured, as described above.

After eighteen hours' incubation, the plates are examined, the in vitro effectiveness of the sulfonamides is determined, and the organisms are identified. (See Table V.)

DISCUSSION

The drug of choice can be determined at the time (eighteen to twenty-four hours) the cultures are positive for growth. In that length of time the organisms most likely have not become drug-fast. Various concentrations of the drugs are used, so that the approximate blood level, necessary for therapeutic effectiveness can be estimated at the same time. Identification of the organisms can be made from the control plates of the experiment, so that duplicate cultures are not necessary.

If the patient's blood contained a high concentration of one of the sulfonamides at the time of the experiments, none of the plates may be positive for growth, since the medium does not contain para-amino-benzoic acid, but growth will appear in the plate to which 1 mg. per 100 c.c. para-amino-benzoic acid has been added. This was not encountered in any of our experiments.

TABLE V

CHART SHOWING INHIBITION OF GROWTH OF HEMOLYTIC STAPHYLOCOCCUS AUREUS IN CULTURE OF WOUND AFTER EIGHTEEN HOURS' EXPOSURE TO SULFONAMIDES

SULFA-NILAMIDE		SULFA-PYRI-DINE	SODIUM SUL-FAPYRIDINE			SULFA-THIAZOLE	SODIUM SULFATHIAZOLE			SULFA-DIA-ZINE	SODIUM SUL-FADIAZINE		
10	20	5	5	10	20	5	5	10	20	5	5	10	20
0	0	0	0	0	0	++++	0	++++	++++	0	0	0	0

The experiments included cultures of blood, nose, and throat, spinal fluid, sputum, and wounds. From these cultures the following bacterial types and strains were isolated: *Diplococcus pneumoniae, Streptococcus hemolyticus,* and hemolytic *Staphylococcus aureus.* This method proved equally efficient for all organisms.

An attempt to correlate the in vitro experiments with the in vivo effectiveness of the sulfonamides is in progress.

CONCLUSIONS

1. A simple, quick method for testing the inhibiting effects in vitro, of sulfanilamide, sulfapyridine, sodium sulfapyridine, sulfathiazole, sodium sulfathiazole, sulfadiazine, and sodium sulfadiazine upon the growth of various bacterial types and strains is described.

2. The drug of choice can be determined as soon as the control cultures are positive.

A SIMPLIFIED METHOD FOR FEEDING RATS

H. Ward Ferrill, Ph.D., Chapel Hill, N. C.

A SATISFACTORY method for placing known quantities of solutions directly into the stomach of white rates becomes more and more important when the number of animals is large and laboratory assistants are unavailable. The author has found the following method very satisfactory over a period of several years; it is simple and eliminates practically all danger of injury to the animal.

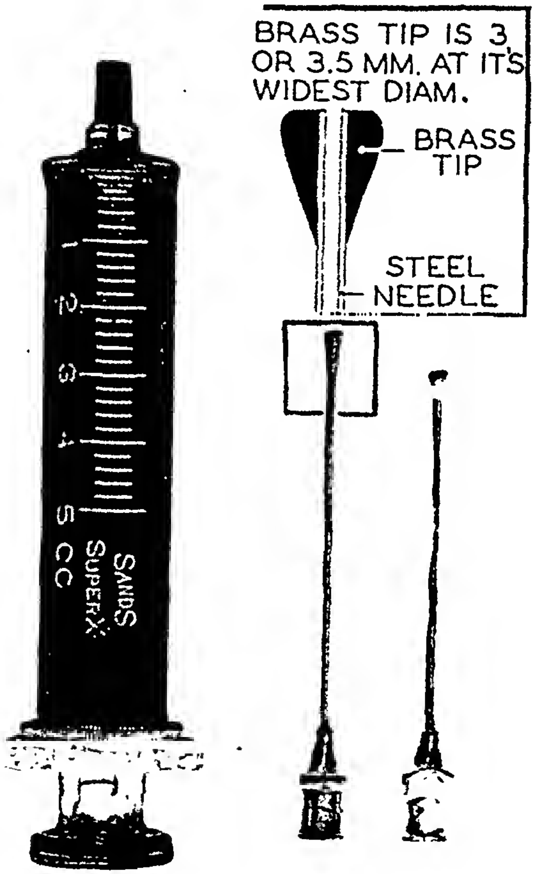

Fig. 1.

An ordinary hypodermic syringe of any desired capacity is used for the accurate measurement of the material. A long, large or small bore needle is used and on its end a small brass knob is soldered. The brass extends far enough up the needle to give it a good area of contact, and an opening the same

*From the Department of Physiology, University of North Carolina School of Medicine. Received for publication, January 29, 1943.

size as the bore of the needle is made through the center of the attached metal. The brass is polished to a very smooth finish so that it can be inserted easily and irritation of the esophagus or cardiac sphincter avoided. It has been found helpful to have different sized needles and knobs for various sized rats if the work is begun when the animals are small. The size which will slip easily down the esophagus of half-grown or adult rats is too large for young animals. The diameters of the knobs used by the author range from 3.0 to 3.5 mm., the smaller being satisfactory for rats of weaning age. A needle at least 2.5 inches in length is more satisfactory than shorter ones.

The animal is held in the left hand with the fingers well forward on the neck to tilt the head back slightly. Then the needle is passed directly down the esophagus into the stomach, and the solution is expelled by pushing in the plunger of the syringe. The animal may clamp the needle with its teeth, but this does not interfere as it does when using a rubber catheter. No gag is necessary for inserting the needle.

Many thousands of injections have been made with this procedure without a single case in which the needle passed into the trachea. The method is very rapid; one person can feed as many as 120 animals per hour after very little training. Autopsies on experimental animals indicate that there is no gross or microscopic change in the esophageal mucosa from daily use of this procedure.

Fig. 1 shows the relative proportions of the various parts of the instrument.

A RAPID METHOD OF PREPARING PNEUMOCOCCAL SPECIFIC CARBOHYDRATES WITH THE AID OF AN ELECTRIC CURRENT*

MARTIN BURGER, M.SC., NEW YORK, N. Y.

THE methods generally used to prepare soluble specific substance of pneumococci[1-3] require autolysis of the cocci. From the autolyzate containing the specific soluble substance and large amounts of protein, the latter is removed. Both the autolysis and the elimination of protein are time-consuming, and we thought it worth-while to investigate a method which would require neither autolysis nor the removal of large amounts of protein.

In 1935, Yen and Kurotchkin[4] and Murao and Morimoto[5] showed that immunologically specific substances could be prepared by electrolyzing suspensions of certain organisms. The former authors obtained the soluble specific polysaccharides of Friedländer's bacillus and *Monilia tropicalis;* and the latter authors obtained a clear filtrate from a suspension of *Bacillus typhosus,* which was said to be more efficient for immunization of mice than a corresponding heat-killed suspension of the same organism.

EXPERIMENTAL

Recent mouse-passed cultures of Types II, III, VI, XII, XIII, XIV, XIX, and XXIII pneumococci were grown for 18 hours in beef-heart broth medium containing 3 per cent of normal horse serum. The organisms were collected

*From the Bureau of Laboratories, Department of Health.
Received for publication, February 17, 1943

by centrifugation and washed twice with 0.85 per cent saline. The average yield of packed cells from ten liters of broth was 15 c.c. The cells were suspended in 150 c.c. of 0.85 per cent NaCl solution, transferred to a 600 c.c. beaker, and layered with 10 c.c. of toluol. A pair of platinum wire electrodes (B. & S. 19 gauge) were placed 6 cm. apart and immersed in the suspension. A variable resistance or bank of lamps in series with the electrodes served to control the voltage across the electrodes. The voltage was maintained between 18 and 22, and the current was 0.45 amperes. A water bath around the beaker was kept between 20° and 22° C., and a thermometer, to note the temperature and at the same time used as a stirrer, was kept in the suspension throughout the electrolysis. The temperature was maintained below 30° C. at all times. The solution was stirred every half-hour in order to remove bacterial protein substances which accumulated on the electrodes. The electrolysis was stopped when the solution became almost transparent. The time required for the dissolution of 15 c.c. of organisms was usually 20 to 24 hours. Most of the precipitated protein which formed was in the toluol layer, and the small amount of suspended matter proved, on microscopic examination, to be bacterial debris and some intact organisms. The latter, however, gave negative Neufeld quellung reactions.

The solution was separated from most of the precipitate by centrifugation, then filtered through filter paper, and the slightly turbid filtrate was further clarified by centrifugation in an angle centrifuge. The clear supernatant was dialyzed for 18 hours against running tap water and finally concentrated in vacuo to one-fifth the original volume of suspension. Any insoluble matter which formed was eliminated by filtration. A small portion of the clear filtrate, when tested for specific polysaccharide, gave an immediate heavy precipitate in homologous antiserum, but not in heterologous antisera. To the main filtrate were added 3 volumes of 95 per cent ethanol. A flocculent precipitate formed, which increased in amount on the addition of 5 c.c. of saturated sodium acetate solution containing 0.5 c.c. of glacial acetic acid. The precipitate, after settling in the refrigerator, was separated by centrifugation, dissolved in 25 c.c. of distilled water, and a 1 c.c. sample tested for the presence of protein. If protein was present (i.e., positive biuret or trichloracetic acid tests), the main solution was shaken with chloroform-butyl alcohol mixture, as recommended by Sevag.[6] Six extractions with the chloroform reagent usually removed all of the protein, as evidenced by negative biuret and trichloracetic acid tests. The polysaccharide was reprecipitated by adding 2 volumes of ethanol, allowed to stand in the refrigerator overnight, and centrifuged the following day. The alcoholic supernatant was discarded, and the precipitate suspended in 95 per cent ethanol, filtered on a Buchner funnel, washed with absolute alcohol, ether, and finally dried in a vacuum desiccator. The average yield of specific carbohydrate from the organisms grown in 10 liters of medium was 125 milligrams.

The substances were type-specific, as no cross reactions were obtained in heterologous antipneumococcal sera. They all gave a positive precipitin reaction in a dilution of 1:10[6] when tested against homologous rabbit antiserum. In the dry state, the substances were yellowish in color and readily soluble in water. One per cent solutions gave negative Millon, Hopkins-Cole, trichloracetic

acid, ninhydrin, biuret, and xanthoproteic acid tests for protein. The Molisch tests were positive, and the Fehling tests before acid hydrolysis were negative. After acid hydrolysis, the Fehling tests were positive.

A control suspension of organisms of each of the types studied was transferred to a thin-walled test tube without electrodes and kept immersed in the main suspension during the electrolysis. The nondissolution of the control organisms was confirmed by negative precipitin reactions on the supernatant after separation of the organisms by centrifugation.

The effect of different electrolytes on the dissolution of pneumococci with the aid of an electric current was also studied. One per cent solutions of $NaCl$, $NaNO_3$, Na_2SO_4, or $NaC_2H_3O_2$ were used as the suspending media. Four, 0.5 c.c. portions of packed Type III organisms (Type XIV and Type II organisms were treated similarly) were transferred to tubes, and each sample of cells was washed twice with one of the appropriate electrolytes. The washed cells were then suspended in 30 c.c. of the appropriate electrolyte, layered with 5 c.c. of toluol, subjected to the electric current, and treated as described above. With each electrolyte, dissolution of the organisms was complete at the end of four hours, as evidenced by the complete clearing of the suspension. Microscopic examination of the precipitate which formed showed only bacterial debris present. Chemical examination proved that the precipitate contained protein. One-tenth cubic centimeter portions of the clear aqueous solution gave positive precipitin reactions with homologous antiserum and no reactions with heterologous antisera. Control tubes containing 2 c.c. of the original suspension and not subjected to electrolysis remained milky.

After each suspension had cleared, it was filtered on a wet filter paper to retain the toluol and most of the precipitate. The cloudy filtrate was then passed through a Berkefeld N candle, and the clear filtrate on diluting with two volumes of 95 per cent alcohol gave a precipitate, which, after standing several hours in the refrigerator, was filtered, washed with absolute alcohol, ether, and finally dried in vacuo. No attempt was made to purify the substances obtained in these experiments because of the small amount isolated. One per cent solutions gave positive Molisch tests, faintly positive biuret tests, and negative trichloracetic acid, sulfosalicylic acid, and xanthoproteic acid tests.

The pH of each suspension before and after electrolysis was:

$NaCl$	– 7.4 before; 8.0 after electrolysis
$NaNO_3$	– 7.3 before; 3.4 after electrolysis
Na_2SO_4	– 7.5 before; 2.8 after electrolysis
$NaC_2H_3O_2$	– 7.7 before; 5.7 after electrolysis

With the exception of the NaCl electrolyte, the pH decreased after electrolysis.

These results may explain the views of Yen and Kurotchkin[4] that the liberation of specific polysaccharide substances during electrolysis in sodium chloride solution is attributable to three factors: (a) The sodium hypochlorite which is formed during electrolysis causes lysis of the organisms; (b) the sodium hydroxide which accumulates combines with bacterial protein; (c) the alkali proteinate is attracted to and precipitated at anode, leaving the specific carbo-

hydrate in solution. In the $NaNO_3$, Na_2SO_4, and $NaC_2H_3O_2$ solutions, probably only (b) and (c) are involved as no sodium hypochlorite is formed.

SUMMARY

A comparatively rapid method of preparing protein-free soluble specific substances of pneumococci is described. The substances obtained may be used in the routine standardization of antipneumococci sera. In our procedure, autolysis is replaced by subjecting a suspension of the organisms in NaCl solution (or in $NaNO_3$, $NaC_2H_3O_2$, or Na_2SO_4 solution) to an electric current. Most of the protein is precipitated during electrolysis. The type-specific capsular polysaccharide is isolated from the aqueous solution of the electrolysate by methods similar to those of Heidelberger, Kendall, and Scherp,[1] and Goebel et al.[2]

I wish to thank Mrs. H. Bucca and Miss A. Berlow for their assistance in the bacteriologic work required in this study.

VENIPUNCTURE IN THE PRESENCE OF EDEMA*

STEVEN O. SCHWARTZ, M.D., CHICAGO, ILL.

CONSIDERABLE difficulty is often encountered in locating a vein for the purpose of venipuncture in the presence of marked edema involving the arms. The most common procedure in these cases has been to cut down on the vein.

The writer wishes to describe a simple method for which no priority is claimed, but which does not seem to be commonly known or employed. The technique is as follows: The patient's elbow is held by the physician in such a manner that the thumb is over the antecubital space. Pressure is exerted by the thumb for a period of from thirty to sixty seconds producing pitting. In the bottom of the resulting "pit" the antecubital veins stand out very prominently, since the edema fluid has been expressed not only from the overlying tissues but from the tissues surrounding the veins as well. So prominent are the veins made by this technique that the use of the tourniquet may occasionally be superfluous.

SIMPLIFIED KLOTZ-MACLACHLAN SOLUTION FOR TEMPORARY COLOR PRESERVATION*

BERT E. STOFER, M.D.
DETROIT, MICH.

AMONG the criteria for the ideal fixing fluid are color preservation, ease of preparation and use, rapid fixation of tissue, low cost, and permanency. It is, of course, difficult to find in a single fluid all these desirable properties. With the advent and popular acceptance of color photography the necessity for permanent preservation of specimens became lessened. A good colored lantern slide is a fine permanent record.

In many cases, where the services of a photographer are not immediately available, the specimen must be preserved for a few hours or days in as near a normal state as possible. At times, the specimen itself may be needed for a single staff conference, student group, or other occasions where a permanent mount is not required but natural appearance is desirable. Here color preservation, ease of preparation, and adequate fixation for future sectioning are the chief considerations.

By use of a suitable fixing fluid the specimen can be photographed, demonstrated, sectioned at leisure, and finally discarded or disposed of otherwise. With such a routine, storage space can be kept to a minimum.

*From the Department of Pathology Receiving Hospital, Detroit, Michigan.
Received for publication, March 3, 1943.

In our search for a solution to meet the requirements of this routine various combinations of the Klotz-MacLachlan[1] two-solution procedure were investigated. By modifying the concentration of some of the constituents we were able to develop one solution which has been satisfactorily used in a number of laboratories for more than one year. It fulfills the criteria of color preservation, ease of preparation, and adequate fixation. It is not prohibitively expensive.

The solution is made as follows:

Artificial carlsbad salt	487 Gm.
Chloral hydrate	175 Gm.
Formalin (40 per cent)	150 c.c.
Distilled water to make	19,000 c.c. (5 gallons)

The formula for artificial Carlsbad salt is five times the amount given by MacLachlan[2] but is otherwise unchanged. This is so reported for convenience in preparing the solution.

Sodium sulfate	110 Gm.
Sodium bicarbonate	100 Gm.
Sodium chloride	90 Gm.
Potassium nitrate	190 Gm.
Potassium sulfate	10 Gm.

Care must be used to add enough of the solution to the jar. At least three, and preferably five volumes of solution must be used for each volume of tissue. The specimen must be kept submerged, and it is our practice to overlay with cotton batting those which float. The concentration of the formalin must be watched, and if the color fades too rapidly 100 instead of 150 c.c. may be used in the formula, but this results in somewhat less adequate fixation. We have noted that the red colors, such as are seen in a superficial vascular area, are heightened for a few minutes or an hour after contact with the fluid. By photographing specimens with these features within the specified time, striking color photographs may be obtained.

Specimens may be preserved from seven to twenty-one days, and with certain types of tissue even longer. Fatty tissue keeps the least well. Cytologic detail is not quite so good as formalin fixation, especially if the blocks are cut after the first week or adequate fluid has not been used. The simplicity and color-preserving qualities, however, are ideal, and for temporary preservation this solution is well suited.

SUMMARY

A modification of Klotz's fixing fluid is suggested which temporarily preserves color, adequately fixes tissue, and avoids excessive technical procedure.

USE OF THE SOUTH AFRICAN CLAWED FROG (XENOPUS) AS AN ASSAY ANIMAL FOR GONADOTROPIC HORMONES*

ABNER I. WEISMAN, M.D., AND CHRISTOPHER W. COATES
NEW YORK, N. Y.

IN 1930, Hogben[1] first showed that anterior pituitary lobe extracts could cause external deposition of ova in the mature female *Xenopus laevis* (South African clawed frog). Following this original observation, other investigators corroborated Hogben's finding, and the use of the female Xenopus as an assay animal for gonadotropic substances then became established in South Africa.

The Xenopus differs from the common variety of American frogs in that it constantly ovulates and accordingly carries the ova in its abdomen. The eggs are extruded in natural life only upon stimulation by the male of the species. The Xenopus has never been seen to extrude any eggs when kept segregated from males under laboratory conditions, unless injected by hormones. Thus, the animal is ever ready to expel its eggs upon proper stimulation. The external deposition of eggs has come to be accepted as a reliable manifestation of gonadotropic activity.

Having previously shown that egg extrusion could be attained by injection of extracts from the urine and the serum of pregnancy, a comparative study of the efficacy of true anterior lobe extracts seemed to be the next logical procedure. In our previous investigations[2, 3] it was demonstrated that deposition of eggs could be induced equally successfully by 100 rat units of chorionic gonadotropin of pregnancy urine and from 30 Cartland-Nelson units or 1,000 international units of equine gonadotropin derived from pregnant mares' serum. The Xenopus thus affords an excellent opportunity to evaluate the comparative gonadotropic activity of the various hormone extracts.

PROCEDURE

The Xenopus unit was based on the deposition of eggs within 6 to 18 hours after a dorsal subcutaneous injection of the hormone tested. The smallest amount of hormone which constantly caused extrusion was defined as one Xenopus unit. For each separate dosage of hormone to be tested two mature female Xenopus frogs were used. Each Xenopus was placed in a two-gallon tank filled one-third with water. Each tank was furnished with a half-inch wire mesh placed one inch above the bottom of the tank to prevent the possibility of the Xenopus eating any of its eggs.

Sixteen tanks were set up for eight different dosages of the powdered gonodatropic factor of sheep anterior pituitary gland.† Tanks A and A′ held

*From the Department of Gynecology of the Jewish Memorial Hospital, and the New York Zoological Society.

Received for publication, March 30, 1943.

†The anterior pituitary gland extract used in this study is prepared by G. D. Searle & Co., Chicago, and is commercially known as Gonadophysin.

frogs injected with 5 rat units; the frogs in B and B′ received 10 rat units; those in C and C′ received injections of 15 rat units; D and D′, 25 rat units; E and E′, 50 rat units; F and F′, 75 rat units; G and G′, 100 rat units; H and H′, 200 rat units.

The animals were all injected through the dorsal lymph space and were kept at room temperature. They were examined periodically up to 18 hours after injection. After 18 hours it was noted that the animals in A, A′, B, B′, C, C′ had not reacted by egg extrusion, while the animals in D and D′ (25 rat units) showed definite evidence of egg deposits. Similarly, the animals in the other tanks that received larger doses also reacted positively.

This entire experiment was repeated the following week with similar results being obtained.

RESULTS

From the data compiled in Table I it will be seen that anterior pituitary gland extracts of sheep are highly gonadotropic in the female Xenopus. Quantitatively, 25 rat units were sufficient to produce external deposits of eggs in these animals. On the basis of this and our previous findings, it must be concluded that even though pregnant mare's serum and pregnancy urine extracts do cause deposition of eggs, true pituitary extracts are more efficacious in producing this reaction and with smaller doses.

TABLE I

MINIMAL AMOUNTS OF GONADOTROPINS WHICH ARE CAPABLE OF INDUCING EGG EXTRUSION IN THE FEMALE XENOPUS LAEVIS

CHORIONIC GONADOTROPINS DERIVED FROM PREGNANCY URINE (2)		CHORIONIC GONADOTROPINS DERIVED FROM PREGNANT MARES' SERUM (3)		GONADOTROPINS DERIVED FROM ANTERIOR PITUITARY LOBE OF SHEEP	
Antuitrin-S	100 rat units[1]	Gonadogen	30 Cartland-Nelson units[3]	Gonadophysin	25 rat units[5]
Follutein	100 international units[2]	Anteron	1000 international units[4]		

[1]Chorionic gonadotropin from human pregnancy urine, Parke, Davis & Co., Detroit, Mich.
[2]Chorionic gonadotropin from human pregnancy urine, E. R. Squibb & Sons, New Brunswick, N. J.

[4]Equine gonadotropin, Schering Corp., Bloomfield, N. J.
[5]Anterior pituitary lobe extract of sheep, G. D. Searle & Co., Chicago, Ill.

Since the Xenopus was found to be so accurate in evaluating the activity of the gonadotropes, the animal has been utilized clinically in the assay of urine. Urines from normal nonpregnant women, pregnant women, patients in the postmenopausal state have been assayed by means of the Xenopus. A Xenopus unit is equivalent to that amount of gonadotropic substance which will cause external egg extrusion in two Xenopus within 6 to 18 hours. The results of our clinical assays are of such interest that they will be published separately in a subsequent publication.

SUMMARY

Extracts of the anterior pituitary gland of sheep when injected into the South African Clawed Frog (Xenopus) were capable of inducing ovulation and external extrusion of eggs with doses as small as 25 rat units. Similar

gonadotropic activity with other extracts are evaluated. The use of the Xenopus frogs for assaying the urine of patients for gonadotropic substances is suggested.

CHEMICAL

ESTIMATION OF SERUM GLOBULIN BY MEASUREMENT OF VISCOSITY OF FORMALIN-TREATED SERUM: PROTEIN PARTITION BY PHYSICAL METHODS*

SAWYER FOSTER, M.D., AND FERNANDO BIGURIA, M.D., BOSTON, MASS.

WITH THE TECHNICAL ASSISTANCE OF MISS MARGARET A. ADAMS, A.B.

INTRODUCTION

SINCE serum proteins are often altered in the course of disease, information concerning their total concentration and the relative proportions of albumin and globulin is important for diagnostic and therapeutic purposes. One of the most widely used methods for obtaining these data is the micro-Kjeldahl chemical determination of nitrogen,[1] in conjunction with the modified Howe's method of separation of albumin and globulin by sodium sulfate.[2] This is a time-consuming and elaborate procedure requiring skilled training.

The falling drop technique devised by Kagan,[3,4] employing physical methods, has simplified the determination of the total protein of the serum. However, no methods comparable in simplicity for measuring the fractions of albumin or globulin appear to be available. The combined chemical and physical method advanced by Barbour[5] for albumin estimation is somewhat complicated; the usual tests for globulin such as the Takata-Ara, formol-gel, etc., are qualitative and indicate only the presence of hyperglobulinemia.

In a previous study[6] a modification of the formol-gel reaction was described for estimating the globulin content of sera in hyperglobulinemia. Confirming Napier's work, which demonstrated the specificity of the formol-gel test for globulin, it was observed that for a 5 per cent purified human albumin solution, the addition of small amounts of formaldehyde caused no change in viscosity. With reference to the blood serum, it was shown by direct measurements that the addition of formaldehyde to the serum increases its viscosity and that the degree of change corresponds to the concentration of globulin.

The modified formol-gel reaction[6] is employed in sera containing abnormally increased concentrations of globulin, which can be estimated quantitatively by the observation of a readily detected change in viscosity. This is determined on samples of serum placed in test tubes and then diluted progressively with physiologic saline and treated with formaldehyde. After standing for a period of twenty-four hours at room temperature, the tubes are shaken vigorously, and a degree of viscosity is noticed in one of the dilutions in which the air bubbles produced by the shaking do not rise to the surface, but remain

*From the First and Third (Tufts) Medical Services, Boston City Hospital, and the Department of Medicine, Tufts College Medical School.

Aided by a grant from the Charlton Research Fund, Tufts College Medical School.

Received for publication, May 17, 1943.

stationary, i. e., the "stationary bubble" end point. In less viscous dilutions the bubbles rise slowly, in more viscous dilutions gelification occurs. The "stationary bubble" end point corresponds to a globulin concentration of 3.1 Gm. per 100 c.c. as determined by chemical methods. From such observations the globulin content of a given serum may be calculated by the formula: Gm. per 100 c.c. globulin $= \frac{3.1}{y}$, where y represents the fraction of 1.0 c.c. of serum present in the dilution showing the above end point. Accordingly this method employs an indirect measurement of viscosity and is limited in its uses to cases of hyperglobulinemia.

In the present study the method has been extended to include all ranges of concentration of serum globulin. Direct measurements of the viscosity of formalin-treated sera were correlated with their globulin content. From these data a formula was derived for the determination of all ranges of concentrations of serum globulin. The final object was to estimate the total protein of the blood serum by the falling drop technique, the globulin by the measurement of the viscosity of formalin-treated serum, and the albumin by subtraction of one from the other. The results obtained by physical and chemical methods were compared.

PART I

DEVELOPMENT OF A FORMULA FOR THE CALCULATION OF THE GLOBULIN CONTENT FROM THE MEASUREMENT OF VISCOSITY OF FORMALIN-TREATED SERUM

A. *Viscosity Measurements on Serums With Hyperglobulinemia.*—Twenty samples of venous blood were taken during the fasting state from 19 patients with hyperglobulinemia. The blood was allowed to clot and the serum drawn off. For each serum a series of tubes was set up, each containing an accurately measured amount of serum ranging from 0.20 c.c. to 1.92 c.c. respectively and then diluted with physiologic saline to a final volume of 2.00 c.c. To each dilution was added 0.1 c.c. U.S.P. formaldehyde. After shaking, the tubes were allowed to stand at room temperature for twenty-four hours.

Depending upon their ability to flow easily through the viscosimeter, two to five dilutions from a series were chosen for direct observation of viscosity with reference to physiologic saline as unity. The viscosity was measured by observing the rate of flow of each dilution in an Ostwald pipette[7] of 2 c.c. capacity immersed in a water bath at a constant temperature of 25°C. The Ostwald pipette was allowed to stand in the water bath for ten minutes in order to reach 25° C. before the rate of flow was measured, and each measurement was repeated 3 times to obtain an average. The viscosity was determined by the formula $V = \frac{T_1 \times S.G.}{T_2}$ Where V = viscosity; T_1 = time of flow in seconds of formalin-treated dilution; T_2 = time of flow in seconds of physiologic saline; and S.G. = specific gravity of formalin-treated dilution. Since the specific gravity need be expressed to only two significant figures this factor becomes 1.0. A total of 66 dilutions were studied for their viscosity.

B. *Globulin Determinations.*—The globulin content of each serum in which the viscosity was measured in the above manner was determined in two ways:

(1) by the "stationary bubble" end point of the modified formol-gel reaction, and (2) by micro-Kjeldahl nitrogen analysis in conjunction with the modified Howe's method of separation of albumin and globulin. The globulin values. obtained by means of the "stationary bubble" end point, compare closely with the values found chemically with an average difference of 5 per cent and individual variations from 0 to 15 per cent (Table I). Since the results obtained by the "stationary bubble" end point could be reproduced more consistently, they were selected as the standard to calculate the globulin concentration of the dilutions prepared from each serum.

TABLE I

GLOBULIN VALUES, GM. PER 100 C.C. DETERMINED BY TWO METHODS

C. *Derivation of Formula Expressing Globulin Concentration in Terms of Viscosity.*—The viscosity values of the 66 dilutions mentioned in Section A were related to their respective globulin values mentioned in Section B. By plotting the globulin values against the log. (viscosity — 1), a straight line was obtained when the globulin concentration of the dilutions was less than 2.5 Gm. per 100 c.c. Above this level the straight line did not persist. The equation of the straight line, determined by the customary method of least squares, was found to be G = 1.55 log. (V-1) + 1.64 where G is the grams of globulin per 100 c.c. and V is the viscosity. Fig. 1 shows all the data and the straight line in the region to which it may be applied.

PART II

APPLICATION OF THE FORMULA G = 1.55 LOG. (V-1) + 1.64 TO THE DETERMINATION OF ALL RANGES OF GLOBULIN IN BLOOD SERUM

Serum was obtained as before and two test tubes were prepared, one containing 2 c.c. of undiluted serum and the other, 1 c.c. of serum diluted with

1 c.c. of physiologic saline. To each was added 0.1 c.c. U.S.P. formaldehyde. The tubes were shaken, and, after a period of 24 hours at room temperature, observations of viscosity were performed as described above. The undiluted serum was used if it was capable of flowing freely through the Ostwald pipette. Otherwise the diluted serum was used. The viscosity reading was substituted in the formula G = 1.55 log. (V-1) + 1.64, and the globulin concentration multiplied by 2 when serum diluted 50 per cent was used. The total protein in each serum was determined by the falling drop technique of Kagan, and the albumin content was obtained by subtracting globulin values from the total protein.

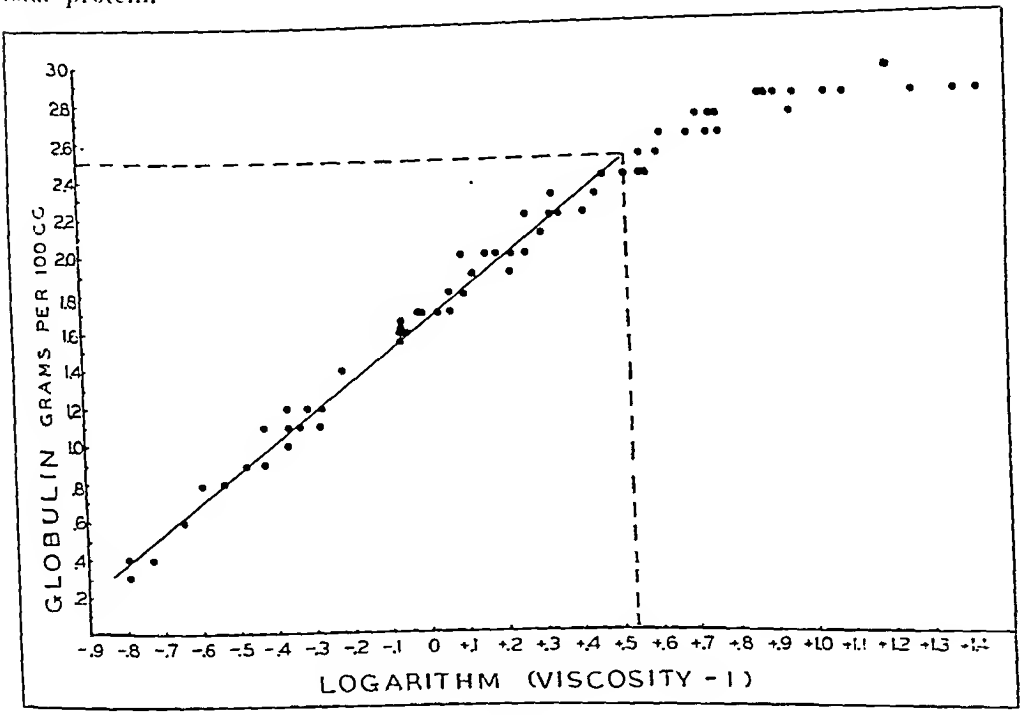

Fig. 1.

The total protein and the globulin and albumin content of 18 sera were determined. The comparative results between the chemical methods and the combined use of the falling drop and the viscosimetric methods are shown in Table II. The differences in globulin content between the chemical and the physical methods varied from 0 to 0.6 Gm. per 100 c.c. with an average of 0.2 Gm. per 100 c.c. and an average percentage difference of 7; the variations in the case of albumin were from 0 to 0.8 Gm. per 100 c.c. with an average difference of 0.2 Gm. per 100 c.c. and a percentage difference of 8. The total protein differences were from 0 to 0.4 Gm. per 100 c.c. with an average of 0.2 Gm. per 100 c.c. and a percentage difference of 4.

Experiments 11, 12, and 13 showed a variation not consistent with the general average. A search for the cause of such irregularity revealed that improper cleansing of the pipettes and especially of the Ostwald pipette was responsible for the abnormal results. When repeated with adequate precautions, the observations were consistent with the earlier determinations.

TABLE II

PROTEIN DETERMINATIONS. COMPARISON BETWEEN PHYSICAL AND CHEMICAL METHODS

		GM. PER 100 C.C.		DIFFERENCES	
		FALLING DROP AND VISCOSIMETRIC METHODS	CHEMICAL METHODS	GM. PER 100 C.C.	PER CENT

		3.8	3.7	+0.1	3

CONCLUSIONS

1. The addition of small amounts of formaldehyde to blood serum produces an increase in the viscosity of the serum. This change is due to globulin, since it does not occur when formaldehyde is added to a 5 per cent solution of purified human albumin.

2. A strictly linear relation was demonstrated between the degree of viscosity and the globulin content of formaldehyde-treated serum, when the globulin content was below 2.5 Gm. per 100 c.c. This relation is expressed by the equation $G = 1.55 \log. (V\text{-}1) + 1.64$ where G = grams of globulin per 100 c.c. and V = viscosity.

3. With this formula it is possible to estimate quantitatively the globulin concentration of the blood serum by measuring its viscosity after the addition of formaldehyde.

4. The value of the viscosimetric method using formaldehyde-treated serum for the estimation of globulin is enhanced when used together with the falling drop method for estimation of total protein. Through their combination the total protein, albumin, and globulin content of any serum can be estimated entirely by physical means with great saving of time, material, and number of personnel.

5. A comparison of the physical and chemical methods shows an average difference of 0.2 Gm. per 100 c.c. for total protein, albumin, and globulin. This error is similar to that inherent to the chemical method.

6. The careful observance of certain precautions must be emphasized: the equipment must be kept meticulously clean; the amounts of serum, saline, and formaldehyde should be measured with accuracy; the water bath must be kept at a constant temperature.

We gratefully acknowledge the assistance we have received from Drs. T. H. Ham and F. H. L. Taylor from the Thorndike Memorial Laboratory, and from Miss Jane Worcester, Associate in the Department of Vital Statistics, Harvard School of Public Health.

A METHOD FOR EXACT PROTEIN DETERMINATION IN SMALL QUANTITIES OF SPINAL FLUID*

F. RAPPAPORT, PH.D., AND E. LASOWSKI, PETAH TIQVA, PALESTINE

ALTHOUGH the knowledge of the exact protein content of the spinal fluid is frequently of diagnostic importance, the present methods when carried out with small quantities of fluid yield results which may show an error as high as 100 per cent.[1] Exact results may, of course, be obtained with the old Kjeldahl method, but this requires such large quantities of fluid that they cannot as a rule be obtained, or only with difficulty.

PRINCIPLE OF THE NEW METHOD

The total proteins of the spinal fluid are precipitated with phosphomolybdic acid, centrifugated, and the sediment, after being dissolved in diluted sodium hydroxide, is quantitatively carried over to a Kjeldahl flask. The further procedures are those of nonprotein nitrogen determinations.[2, 3]

REAGENTS

1. For protein precipitation:

(a) Dissolve 5 Gm. of anhydrous sodium sulfate and 8 Gm. of phosphomolybdic acid in 200 c.c. distilled water.

Add 20 c.c. of 5N sodium hydroxide, and boil the mixture for one-half hour. After cooling, add 10.6 c.c. of concentrated sulfuric acid and water up to 1000 c.c.

(b) A 4 per cent solution of chemically pure sodium hydroxide.

2. For digestion:

Dissolve 1 Gm. of phosphomolybdic acid in about 50 c.c. of water. Add 1 c.c. of Kjeldahl hydroxide and boil for twenty minutes to drive off the possibly present ammonia; add 30 c.c. of concentrated sulfuric acid and 5 c.c. of syrupy phosphoric acid. Add water to make up 100 c.c.

3. For neutralization:

(a) A 27 per cent solution of chemically pure sodium hydroxide.

(b) Dissolve 15 mg. of methyl red and 60 mg. of thymol blue in 20 c.c. of N/1 NaOH and add water to 1000 c.c.

(c) A saturated (about 5 per cent.) solution of sodium fluoride.

To make this reagent (3) mix 6 parts of solution a with 1 part of solution b and 3 parts of solution c. This mixture keeps indefinitely.

4. For titration:

(a) Buffer solution. Dissolve 84.5 Gm. boric acid and 15.6 Gm. sodium hydroxide in about 800 c.c. water. Boil vigorously for thirty minutes to remove NH_3. Cool and add water to 1000 c.c.

*From the Biochemical Laboratory of the Beilinson Hospital, Petah Tiqva, Palestine.
Received for publication, April 8, 1943.

(b) Dissolve 20 Gm. of sodium bromide in a little water in a measuring flask. Add 8 Gm. elemental bromine and water to 1000 c.c. Just before using pour 10 c.c. of solution (b) into a 50 c.c. measuring flask. Add 25 c.c. of buffer solution and water to 50 c.c.

(c) Potassium iodide in granules.

(d) Fuming hydrochloric acid diluted with an equal quantity of water.

(e) 0.25 per cent starch solution.

(f) N/100 solution of sodium thiosulfate.

PROCEDURE

Place in a small 5 by 50 m.m. test tube (Widal tubes are best) exactly 1 c.c. of the spinal fluid. If the Pandy reaction is positive, only 0.5 c.c. of fluid is used. Add 2 c.c. of phosphomolybdic acid reagent (1a) to precipitate the proteins. Place in water bath at 56° C. for a few minutes; then centrifuge for about ten minutes at 3,000 revolutions. Carefully pour off the supernatant fluid and dissolve the sediment in 0.3 to 0.5 c.c. of 4 per cent sodium hydroxide (1b). Draw up the contents of the tube with great care, using a serologic 1 $cm._3$ pipette: and place them into a Kjeldahl flask which contains 2 c.c. of the digestion mixture reagent (2) and a few glass pearls. Again fill the tube with some water, and with the same serologic pipette transfer it to the Kjeldahl flask. Repeat this a number of times drawing up and blowing out the contents of the pipette and washing the sides of the tube. Set up two Kjeldahl flasks with the fluid to be examined and two flasks filled only with the phosphomolybdic acid reagent as blanks. Boil both series with the digestion reagent until the contents of the flasks become colorless and fumes no longer arise. After cooling the flasks, dilute the contents of each with 2 to 3 c.c. of water, and while continuously cooling with water, add, drop by drop, the mixed indicator, NaOH, sodium fluoride solution (3) until it turns blue: all flasks require about the same number of drops. Neutralize, therefore, all the flasks in the series in this manner; then add to each 5 c.c. of the hypobromine solution (Reagent 4b mixed with buffer solution 4A for use). Then add to each a few granules of potassium iodide (4c) and 2 to 3 c.c. of diluted hydrochloric acid (4d). Titrate with N/100 thiosulfate (4f) solution until the mixture is straw yellow. Add starch and continue titration until the colorless end point is reached.

Note: We use for our determinations micro-Kjeldahl flasks whose dimensions are: length of flask, 135 mm.; diameter of neck, 20 mm.; length of neck, 85 mm.; diameter of body of flask, 40 mm.; volume of flask, about 35 c.c.

CALCULATION

1 c.c. of N/100 thiosulfate equals 0.046 mg. nitrogen, which multiplied by the protein number 6.25 corresponds to 0.2875 mg. of protein. This figure multiplied by 100 gives the protein content as mg. per 100 c.c. Example: 2.1 c.c. thiosulfate for 1 c.c. of spinal fluid was used. Calculation: $2.1 \times 0.2875 \times 100 = 60.375$ mg. protein per 100 c.c. of fluid.

The quantity of thiosulfate used is calculated by subtracting the quantity used in the unknown from that in the blank.

The application of this method for the determination of albumin, globulin, and nonprotein nitrogen in spinal fluid will be discussed in another communica-

tion. We shall also report our findings on the protein content of normal spinal fluid as determined by this method.

CONCLUSION

A method is described by which exact protein determinations are possible even in very small quantities of spinal fluid.

A HISTOCHEMICAL METHOD FOR DEMONSTRATING THE PRESENCE OF SULFONAMIDES IN THE TISSUES*

George M. MacKee, M.D., Franz Herrmann, M.D., Rudolf L. Baer, M.D., and Marion B. Sulzberger, M.D., New York, N. Y.

A RECENT communication[1] reported the development of new vehicles ("Penetrasols"), which increased the penetration of a large variety of substances through grossly intact skin (for example, "protein" allergens, iron, mercury, bismuth, and the sulfonamides). The penetration of externally applied sulfonamides was demonstrated by the presence of these drugs in the blood and urine. Further evidence of the penetration of sulfonamides into and through the skin, was adduced by biopsy of the skin area and the use of a newly developed specific histochemical color reaction with the sulfonamide.

We report here the details of our method, which we believe may find many other applications. Preliminary report has appeared.[2]

The vehicles studied were of different compositions, but in each instance equal quantities of the vehicle, containing equimolecular concentrations of the drug, were gently rubbed in, in identical manner to skin areas of identical size. The only preceding preparation consisted of clipping the hairs of the guinea pigs as short as possible with a sharp pair of scissors.

General ether anesthesia was used in the guinea pigs; and local anesthesia with procaine in man. A type of block anesthesia was employed through injection of the anesthetic around and well away from the site of excision to eliminate all possible procaine contamination of the excised tissue. This is an indispensable precaution, as the presence of procaine, or even of injected water, could produce erroneous results. The line of excision must be kept at a considerable distance from the site of inunction to avoid displacement of the inunction material with the scalpel. Each excision was performed after a given time had elapsed following inunction.

PROCEDURE OF TISSUE EXAMINATION

A. *Fixation.*—No liquid fixatives could be used to obtain a *histotopical* demonstration, i.e., a demonstration of the drug's localization and distribution within tissue, because it was evident that significant quantities of sulfonamide might be removed or displaced through transportation with the liquids. To overcome these difficulties, we used a gaseous, instead of a liquid, fixative.* Dry formaldehyde gas was chosen because the use of osmic acid fumes would have obscured our findings. Fixation was carried out as follows: Trioxymethylene (paraformaldehyde) powder is spread in about 1 cm. depth over the bottom of small glass beakers (1 to 4) which are placed within a glass jar and their bases surrounded by 1 cm in depth of powdered trioxymethylene. The jar must be equipped with a well-fitting glass cover (an ordinary butter jar, 4 × 4 × 3 inches, will do). The small beakers are roofed, either with a piece of gauze fixed by a rubber band, or with a small glass lattice. The biopsy specimens are placed flatly on these "sieves." Each beaker is clearly marked to keep a record of the specimens. After the small beakers with their fresh specimens have been placed within the larger jar, the latter is covered and kept closed throughout the experiment by several windings of adhesive tape around the line of closure.

The jars are kept at room temperature and fixation takes place within two to twenty-four hours, depending on the size and thickness of the specimens. The most favorable moment for microtome cutting is immediately after fixation, because some shrinkage and brownish discoloration gradually occur; but, when necessary, satisfactory sections can be obtained even after ten to fourteen days.

B. *Cutting of Sections.*—After fixation, frozen sections of 10 to 20 μ are cut. As our particular purposes necessitated comparable specimens, the sections used were all made of approximately equal thickness (about 16 μ).

In the study of skin penetration, as already stressed by Fuerbringer[3] and later on by others (Zwick, Eller and Wolff, and Duemling[4]), the specimen must be kept in such a position on the freezing table that the epidermal surface is kept toward the operator, never directed toward the knife. This tends to obviate the possibility of carrying material from the epidermal surface into the deeper structures with the movement of the knife. In cutting thin and hairy animal skin, the epidermal part often tends to separate as a thin lamella. This can be overcome by placing the specimen sagittally, at an angle of about 90 degrees to the edge of the knife. Here again, the epidermal surface must be turned away from the knife while cutting.

C. *Chemical Process and Reagents Used.*—The demonstration of sulfonamide within the tissue is based on the formation of a characteristic precipitation. Identification by means of formation of sulfonamide crystals, as carried out with a solution of iodine and sodium iodide, etc., in microchemical analysis[5] is not feasible in histotopical studies because the drug would be displaced from its original site. Similarly Marshall's reagent, commonly used for quantitative sulfonamide analysis, cannot be employed because extraction would occur with the diazotation and with the reaction.

"Ehrlich's Reagent." p-dimethylaminobenzaldehyde, as used by Werner and others[6, 7, 8] for quantitative sulfonamide analysis in blood, urine, and

*For the same reasons we found these technical precautions necessary in other histotopical examinations; i.e., in our studies on the penetration of Fe., Bi., Hg. etc., through the skin.

other biologic fluids, proved most suitable for our purposes. Extensive preliminary trials in vitro and in tissue sections, with solutions of this reagent in water containing various concentrations of mineral acids in acid alcohol, etc., have shown optimal precipitation with the following solution:

p-dimethylaminobenzaldehyde	1.0 Gm.
Alcohol abs.	95.0 c.c.
Concentrated HCl	5.0 c.c.

The purest obtainable aldehyde, having little, or at most a light buff color when dry, is used. The solution is kept in an amber-colored flask, well closed by a ground glass stopper. The liquid gradually becomes yellowish, and it is preferable to use fresh solutions (never more than 2- to 3-weeks-old).

This reagent yields a lemon-yellow precipitate with low concentrations of free sulfonamides and an orange shade with higher concentrations of the drugs. The reacting group of the sulfonamides is their free "aniline," NH_2 group. Because the colored reaction product bleaches out and gradually assumes other shades on exposure to the air, in vitro as well as in the tissue, the sections cannot be made to keep the characteristic color for long. Extensive studies attempting to defer the fading time and to avoid any procedures or admixtures which might tend to produce variation in color have resulted in the adoption of the following routine technique which we have carried out satisfactorily for the past two years on a great number of specimens of human and animal skin.

The sections (16 μ), obtained as described above, are placed *directly* on a clean slide, with a dry brush (camels' hair). Two drops of the p-dimethylaminobenzaldehyde solution in acid alcohol (see above) are dropped on the section. After three to five minutes, 1 to 2 drops of absolute alcohol containing 5 per cent of concentrated HCl are added (1 drop for the smaller and 2 drops for the larger sections). The sections are dried immediately by careful absorption of excess fluid with small pieces of filter paper, or before a rotating fan, or by both methods. (Careful studies under controlled conditions ruled out the possibility that the removal of the acid-alcohol with filter paper could cause displacement of the colored product in the section.) Warming is not advisable. As soon as dry, the sections are covered with the following concentration of dissolved Damar resin: Damar resin 10.0 Gm., Xylene 10.0 c.c. (This "thick" mounting medium has proved superior to Canada balsam, cedar oil, origanum oil, albumen-glycerin, etc., which either extract the colored product, or produce color changes, or lead to quick fading.) Then the cover slip is sealed with liquid paraffin melting at 56° C. Because exposure to air impairs the intensity of the color, after the addition of the acid alcohol the whole procedure must be accomplished as quickly as possible and air bubbles must be removed from under the cover slip. The successive use of acid alcohol and the solution of Damar resin in xylene has the additional advantage of producing a satisfactory and rapid clearing of the sections. Microscopic examination must be as early as possible; and colored photos, if desired, should be taken not later than three to four hours after the reaction has occurred.

As stated, the presence of sulfonamide is characterized by a bright orange or lemon-yellow color. Counterstaining has not proved valuable because the reaction color of the sulfonamide tends to be obscured. Black and white photo-

graphs may show the sulfonamide picture and distribution when the tissues themselves do not contain pigment or other material darker in shade than the orange-yellow sulfonamide reaction.

Figs. 1, 2, 3, and 4 are black and white photographs which were retaken from colored diapositives and which show the different routes of penetration of sulfonamides through the skin of *the same* albino guinea pig after inunction of sulfonamide under strictly comparable conditions, but dissolved in 3 different types of vehicles. The photographs are presented here merely to show the technical possibilities of our method in differentiating various types of distribution in the tissues. (Details on composition of the different vehicles and mode of application, etc., will be the subject of forthcoming communications.)

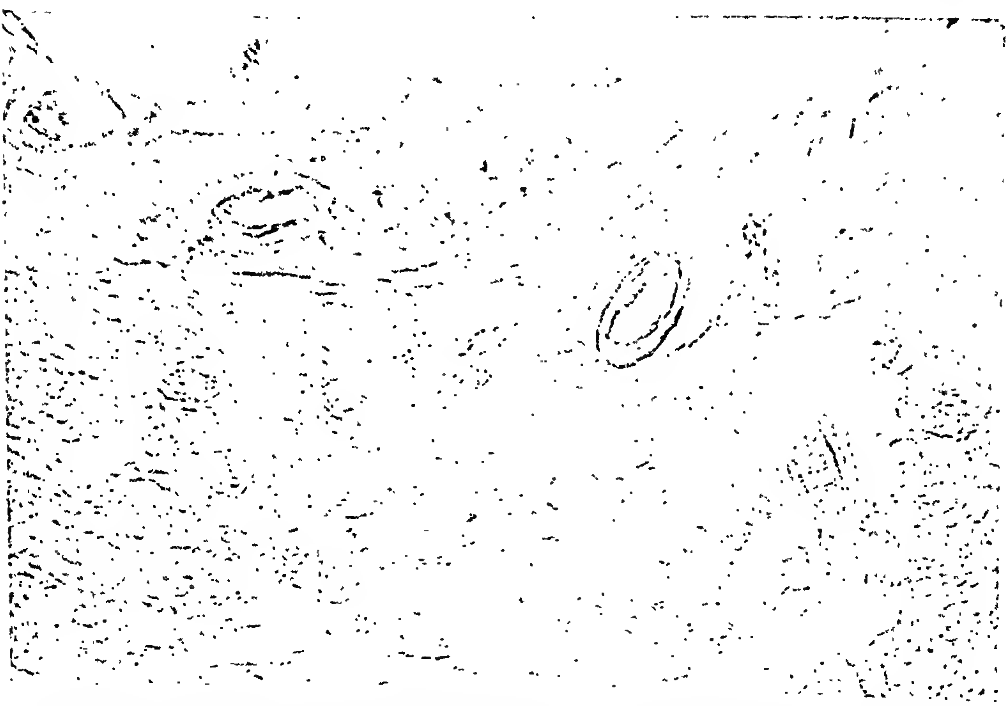

Fig. 1.—Control: Area of skin which received no preceding inunction but which was excised and histologically prepared and treated with p-dimethylaminobenzaldehyde in acid-alcohol exactly like the other sections shown in Figs. 2 to 4. No reaction seen.

Figs. 1 to 4.—Figures are all of specimens of biopsies taken from different skin areas of the same albino guinea pig. (Black and white reproductions of colored diapositives). (Particulars on the composition of the penetrating vehicles designed to achieve the different effects will appear in a future publication.)

D. *Controls.*—Several controls are essential to make as certain as possible that the yellow to orange color observed in the sections is actually due to a sulfonamide reaction and not to the presence of preformed yellowish material or pigments (e.g., melanin, blood pigments, carotene, bile, etc.).

Control 1: Examination of several sections from the same tissue specimen processed in identical fashion as the sections treated with p-dimethylamino-benzaldehyde, but *not* exposed to this reagent. Comparative examination of these sections either shows that preformed colored matter is absent, or reveals the site of any preformed colored matter of a shade similar to that of the sulfonamide reaction product. As a rule, skin sections show little or no mate-

other biologic fluids, proved most suitable for our purposes. D. *Controls.*—Several controls are essential to make as certain as possible that the yellow to orange color observed in the sections is actually due to a sulfonamide reaction and not to the presence of preformed yellowish material or pigments (e.g., melanin, blood pigments, carotene, bile, etc.).

Control 1: Examination of several sections from the same tissue specimen processed in identical fashion as the sections treated with p-dimethylamino-benzaldehyde, but *not* exposed to this reagent. Comparative examination of these sections either shows that preformed colored matter is absent, or reveals the site of any preformed colored matter of a shade similar to that of the sulfonamide reaction product. As a rule, skin sections show little or no mate-

rials in the color range of the sulfonamide reaction; and, if present, their color is duller and more brownish than that of the specific sulfonamide product, which, as stated, is characterized by its brightness.

Fig. 2.—Area of skin which received inunction of 10 per cent sulfonamide, applied in a vehicle consisting of lanolin and water. (Excision sixty minutes after inunction; fixation and treatment as described in text.) Note that the reaction product (darker areas) is practically confined to the surface and the upper parts of the horny layer.

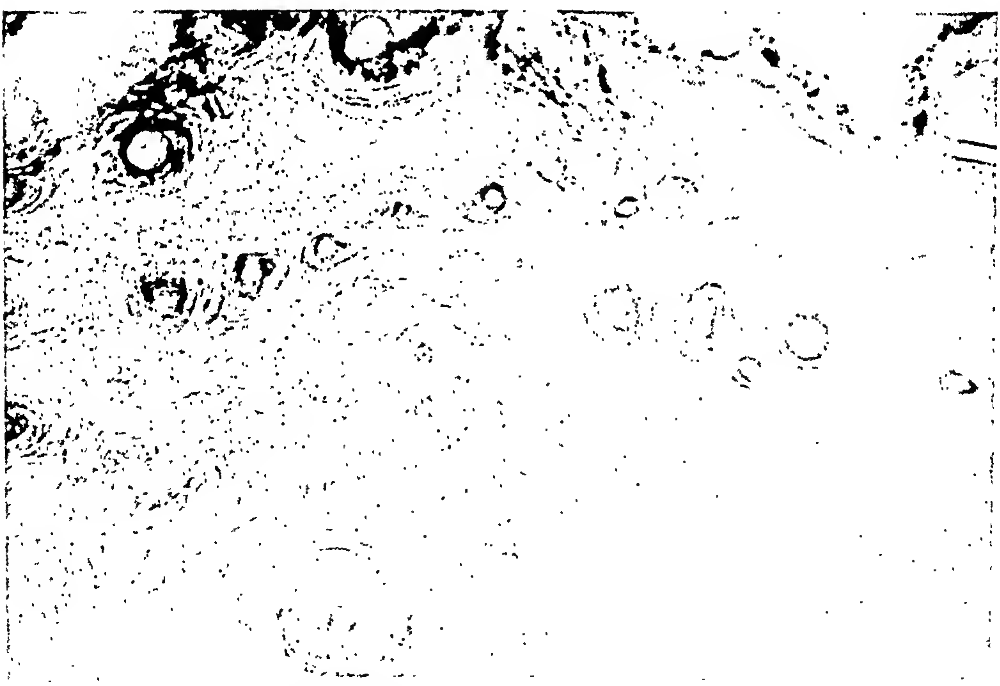

Fig. 3.—Area of skin which received inunction of 10 per cent sulfonamide dissolved in a penetrasol type of vehicle which favors penetration into horny structures. (Excision sixty minutes after inunction; fixation and treatment as described in text.)

(Note that the horny layer and the follicle cross sections show heavy deposits of the dark material, while other parts are relatively free.)

Control 2: Comparative examination of a specimen of the same or corresponding organ but obtained from a site known to be *free of sulfonamide.* Control biopsy specimens taken from the same individual at a skin area distant from that of the sulfonamide application, are fixed, cut, and treated with

p-dimethylaminobenzaldehyde, exactly as described for the demonstration of sulfonamides in the tissue. This is necessary to rule out the possibility of a "nonspecific" reaction. While these controls were uniformly negative (Fig. 1), it must be borne in mind that p-dimethylaminobenzaldehyde produces a yellow reaction with any primary aromatic amine, with urobilinogen, with higher concentrations of urea, and perhaps also with decomposition products of the tissue. We have sometimes observed this phenomena on merely warming a section. (Thus, as stated, warming must not be used in the drying procedure.) Furthermore, certain drugs other than sulfonamides (e.g., phenacetin, acetanilid) give reactions similar to those produced with sulfonamides. Procaine and related local anesthetics may also produce this effect; therefore, as already mentioned, no such solutions should be used to infiltrate the actual site of biopsy.

Fig. 4.—Area of skin which received inunction of 10 per cent sulfonamide in a penetrasol type of vehicle which favors penetration of all cutaneous structures. (Excision sixty minutes after inunction; fixation and treatment as described in text.) (Note that the reaction product [dark material] is found in all structures, including cutis.)

When all precautions have been rigorously observed, the described histotopical method is probably applicable to a large variety of tissues (urethra, other mucous membranes, tonsils, bone marrow, wounds, etc.), but is not likely to prove applicable to certain other tissues (liver, gall bladder, etc.). As is evident, the investigator should not rely upon an *absolute* accuracy of localization; however, when identical experiments *repeatedly* show the *same* localizations of the characteristic colored material; and, conversely, when deliberate experimental modifications *repeatedly* show characteristic *differences* in the localization of the colored material, the findings may be considered as elucidating

particulars of the drug's penetration, route, and distribution within the tissue structures. (See Figs. 2, 3, and 4.)

E. *Discussion.*—A few general comments should be made on our histochemical procedure itself and how we came to adopt the various steps finally selected.

As shown by Morris in reporting on sulfonamide determination in body fluids,[7] the compound responsible for the color is p-dimethylaminobenzylidene-p-aminobenzene sulfonamide. While Morris rightly stressed the dependence of the color on the pH, addition of a buffer is not necessary in our procedure, which is carried out almost in the absence of water. The HCl concentration used is so high that variations which may be caused by pH differences in the specimens are negligible.

In order to minimize the possibility of dissolving or moving parts of the reaction product, our sections are not immersed in the reagent solution, but are treated with the reagent directly while on the slide. On the other hand, the plain acid (HCl)-alcohol is added as a rinse, to ensure the removal of excess reagent and of other loose yellow or orange-colored matter. This rinsing unavoidably involves the loss of a fraction of the reaction product, but we believe this disadvantage to be more than offset by the advantage of confining the colored reaction product as strictly as possible to the original actual sites of the drug within the tissues. Our results are, therefore, more inclined to miss some of the sulfonamide, rather than to indicate sulfonamide where none was present in the tissues.

As already pointed out, the characteristic picture is not preserved for long, despite all available technical precautions to prevent fading. While undeniably inconvenient, the lack of stability of the color is further proof of the nature of the colored product and indicates that the yellow or orange material is produced by the chemical reaction with the sulfonamide and that it is not due to the presence of other or preformed colored matter, such as pigment, lipids, carotene, etc.

SUMMARY

A new method for histochemical and histotopical identification of sulfonamides in tissue sections is described and discussed. This method has been employed and found satisfactory in numerous studies on the percutaneous penetration of sulfonamides, after their solution in penetrating vehicles and their external application to grossly intact human and animal skins.

THE DETERMINATION OF ALBUMIN AND GLOBULIN IN BLOOD SERUM BY SPECIFIC GRAVITY MEASUREMENTS*

R. A. Mortensen, Ph.D., and Margaret Hardinge, A.B.
Loma Linda, Calif.

Specific gravity methods[1-4] suitable for the determination of total protein in serum may be applied to the estimation of the albumin and globulin fractions. In a procedure described by Barbour,[5] serum is mixed with an exactly equal volume of saturated ammonium sulfate under oil and is spun in an angle centrifuge for an hour at high speed. The density difference between the supernatant liquid and a like mixture, in which serum is replaced by an accurately standardized dilute solution of ammonium sulfate, gives the basis for calculating the amount of albumin present. Certain rigorous precautions are necessary. On account of the great difference in the specific gravities of serum and saturated ammonium sulfate, a small error in measuring the volume of either solution makes a large error in the result. The necessary degree of precision is seldom attained in routine work.

In the method here described, prolonged centrifuging is unnecessary and the difficulties involved in the determination of the increase in specific gravity due to protein in the presence of high salt concentration are obviated. After precipitation with ammonium sulfate, the globulin fraction is treated with trichloroacetic acid in order to dilute the salt. It is then redissolved in dilute sodium hydroxide. The difference between the specific gravity of the resulting solution and that of a blank, prepared from an equal volume of the trichloroacetic acid supernatant similarly treated with sodium hydroxide, is a function of the protein content of the solution. Globulin and albumin are calculated from this difference and the specific gravity of the original serum. This procedure permits the specific gravity measurements to be made on dilute solutions and within the range used on serum itself. Only ordinary care is required in order to obtain reliable and reproducible results.

METHOD

Reagents.—Ammonium sulfate solution prepared by adding 346 Gm. of the anhydrous salt to 1000 Gm. of water.

Trichloroacetic acid solution, 5 per cent.

Sodium hydroxide solution, 2.25 per cent.

*From the Department of Biochemistry, School of Medicine, College of Medical Evangelists.

Received for publication, June 7, 1943.

This work was aided by a grant from the Alumni Research Foundation of the College of Medical Evangelists.

Procedure.—One cubic centimeter of serum is pipetted into a 15 c.c. conical, graduated centrifuge tube, and 10 c.c. of the ammonium sulfate solution is gradually added while shaking. It is then corked and centrifuged at 2500 to 3000 revolutions per minute for ten minutes. The supernatant liquid is drawn off to the 1.0 c.c. mark and discarded. Ten cubic centimeters of 5 per cent trichloroacetic acid are added and thoroughly mixed with the precipitated protein, using a fine glass rod to break up any coagulum which may be packed in the bottom of the tube. The mixture is now centrifuged a second time at the same speed for five minutes. One-half cubic centimeter of the supernatant liquid is transferred to a test tube for use as a blank; the remainder is drawn off to 0.5 c.c. One and one-half cubic centimeters of 2.25 per cent sodium hydroxide are added to both tubes and the resulting solutions are thoroughly mixed. The precipitated protein is best stirred up to form a paste before the addition of sodium hydroxide and then stirred again immediately afterwards until the protein is completely dissolved.

The specific gravities of the two solutions are measured by any suitable method, such as the well-known falling drop.[2, 3]

In making a series of determinations, is it unnecessary to prepare a blank for each analysis. In fact, it has been found possible to use the same blank reading over a period of several weeks, provided the reagents are kept in well-stoppered bottles.

Calculations.—The globulin, G, in Gm. per 100 c.c., is calculated from the formula

$$G = 695\ D - \frac{T}{10} \tag{1}$$

where D represents the difference in specific gravity between the blank and the protein solution, and T represents the total protein content of the serum in Gm. per 100 c.c.

If measurements are made with the specific gravity pipette, provided with a scale reading directly in percentage of protein as previously described,[4] formula (1) becomes

$$G = 2\ D - \frac{T}{10} \tag{2}$$

in which D is simply the difference between the readings of the blank and the protein solutions.

Albumin is calculated by subtracting the value of the globulin fraction from the total protein.

Example.—A serum specimen was found by the specific gravity method to have a total protein content of 6.8 Gm. per 100 c.c. When analyzed by this procedure, using the falling drop technique of Barbour and Hamilton,[2] the blank and the protein solutions gave apparent density differences, as read from the alignment chart, of 0.0050 and 0.0091, respectively. Substituting the values in formula (1) gives globulin.

$$G = 695\ (0.0091 - 0.0050) - \frac{6.8}{10} = 2.2 \text{ Gm. per } 100 \text{ c.c.}$$

With the specific gravity pipette[4] calibrated to read directly in total serum protein percentage, the readings of the blank and the protein solutions were

5.80 and 7.25 when reduced to the same temperature. Using formula (2) the globulin content is

$$G = 2\ (7.25 - 5.80) - \frac{6.8}{10} = 2.2 \text{ Gm. per 100 c.c.}$$

Remarks.—In carrying out the foregoing procedure, a centrifuge tube should be used which is known to be accurate at 0.5 and 1.0 c.c.

It is important to add the first 2 c.c. of ammonium sulfate solution to the serum a drop or two at a time with shaking; otherwise, the precipitate may be too voluminous. But with this precaution it will seldom occupy a volume greater than 0.6 c.c. In rare cases it may be necessary to centrifuge for a longer time than ten minutes in order to get a clear supernatant liquid. Turbid solutions may result from failure to tightly cork the centrifuge tube.

For drawing off the supernatant solution after centrifugations, it is convenient to use a tapered glass tube connected to a water-aspirator pump. With suction applied to this tube, the solution may be drawn off rapidly and precisely to the required volume without disturbing the precipitate.

The second centrifugation should not be unnecessarily prolonged, as excessive packing of the protein precipitate retards its solution in sodium hydroxide. At times small gel-like particles which dissolve slowly form upon the addition of alkali. Little or no difficulty from this source is experienced, however, when the mixture is stirred immediately.

Small amounts of the ammonia formed in the reaction of sodium hydroxide with the ammonium salt are unavoidably lost; however, the solution may be allowed to stand for as long as an hour after the addition of alkali without introducing significant error, provided the tube is kept well-corked.

With a little experience a complete serum protein analysis can be made in one-half hour, and four or six determinations can be carried out simultaneously in less than one hour. The method is especially suited to the occasional estimation of serum protein fractions, since the reagents are readily prepared and do not require accurate standardization. With the falling drop method no standard other than that commonly used in measuring the specific gravity of serum is required, while the use of the specific gravity pipette dispenses with the need of a standard solution of any kind.

RELATIONSHIP BETWEEN SPECIFIC GRAVITY AND PROTEIN CONTENT

The specific gravity method for the determination of the total protein content of serum is based upon the investigations of Moore and Van Slyke,[1] Weech, Reeves, and Goettsch,[6] Kagan,[3] and Nugent and Towle,[7] who found that a linear relation exists between specific gravity and amount of protein, having the form

$$\text{Total protein} = K\ (\text{specific gravity} - b)$$

where K is a conversion constant and b represents the specific gravity of serum with protein eliminated. Thus, the specific gravity increment of protein, i.e., the contribution made to the specific gravity by the protein present, is directly proportional to the protein content.

Assuming a similar relationship to exist for protein after having been precipitated and redissolved in sodium hydroxide, it follows that the percentage of

globulin present in the serum in the foregoing procedure may be expressed by the general formula

$$G = \frac{k\ a\ V_f\ D}{(a-b)\ V_s} - \frac{b\ T}{a-b} \qquad (3)$$

in which V_s is the volume of serum used, D is the increase in specific gravity due to the presence of protein, k is a proportionality constant, a is the total volume in cubic centimeters of one-half saturated ammonium sulfate, b is the volume remaining after drawing off the first supernatant solution, V_f is the final volume of the solution after the addition of alkali, and T is the total protein in the original serum in Gm. per 100 c.c.

This equation was tested in an extended series of experiments, using different amounts of pooled human serum analyzed for protein by the Howe[8] technique in conjunction with the macro-Kjeldahl nitrogen method. It was found to hold within rather narrow limits over the range of globulin values likely to be encountered. At the same time, the value of constant, k, was found to be 316.

A comparison of this value for k with the corresponding constant in the formula of Weech and co-workers[6] for total protein in serum, where K is taken as 348, indicates that the apparent specific gravity increment of protein under the conditions in the present procedure is about 10 per cent greater than in the case of pure serum. This difference is probably due to a combination of factors, the most important of which is the retention of a certain amount of trichloroacetic acid by the precipitate. That such a retention occurs was demonstrated by Dulière and Minne.[9] The amount retained was found to be proportional to the weight of protein, however; hence, this factor should not affect the validity of formulas (1-3).

Formula (1) may be obtained by substituting into equation (3) the numerical values designated in the procedure, thus

$$G = \frac{316 \times 11 \times 2\ D}{10} - \frac{T}{10} = 695\ D - \frac{T}{10}$$

Formula (1) reduces to formula (2) when specific gravities are replaced by their percentage protein equivalents as given with the direct-reading pipette.

Small departures from the quantities specified in the procedure are possible if the relationships expressed in equation (3) are taken into account. For example, the final volume of solution may be made 1.5 c.c. instead of 2.0 c.c. by the addition of only 1.0 c.c. of sodium hydroxide solution, provided 1.5 is used as V_f in place of 2.0 in calculating the result. There are practical limits to such variations, however. The addition of too small an amount of alkali, for example, results in failure to completely dissolve the protein precipitate, while an increased amount magnifies the effect of errors in the measurement of specific gravity.

In establishing suitable concentrations and volumes for the solutions involved in this method an experimental study was made of the variations in specific gravity with the composition of different mixtures, both with and without protein present. When 2.25 per cent sodium hydroxide was mixed in different proportions with a solution consisting of 10 volumes of 5 per cent trichloroacetic acid and one volume of one-half saturated ammonium sulfate,

the specific gravity of the resulting solutions varied according to curve ACB shown in Fig. 1. With 1.5 per cent protein present the curve EF was obtained. An amount of protein equivalent to this, for example, appears in the final alkaline solution when a determination is carried out on a one cubic centimeter specimen of serum containing 2.3 per cent globulin and 7.0 per cent total protein. The elevation of any point in EF above the corresponding point in CB represents the specific gravity increment, D, in equations (1-3). This quantity is interpreted as due to and proportional to the protein content of the solution. The line EF also represents the approximate maximum range through which the proportions of the two solutions may be varied in carrying out a determination.

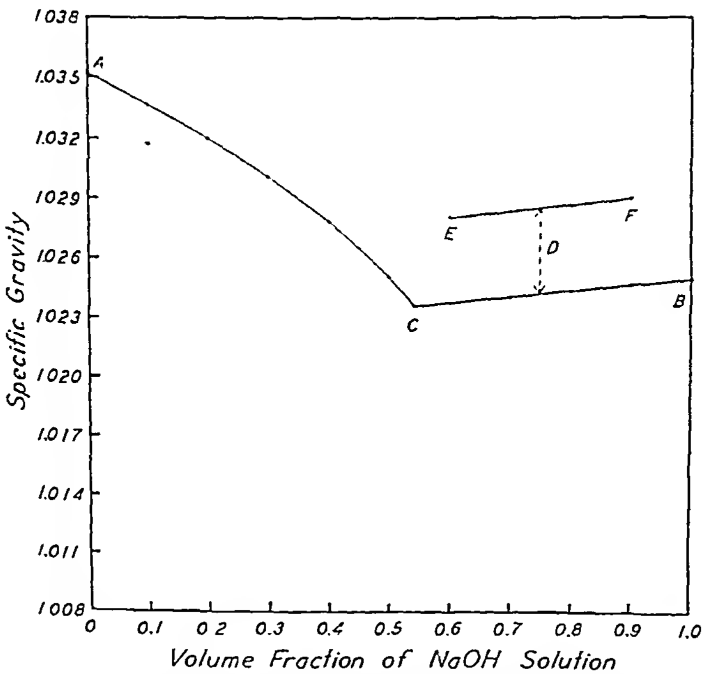

Fig. 1.—Curves representing specific gravity of mixtures of 2.25 per cent NaOH and a solution prepared by adding 10 volumes of 5 per cent trichloroacetic acid to one volume of half saturated ammonium sulfate. Curve ACB, solution containing no protein; curve EF, containing protein. Broken line D represents the increase in specific gravity caused by the presence of protein. Abscissas represent the volume of NaOH solution divided by the sum of the volumes of the two solutions.

RESULTS

Twenty-four determinations by the specific gravity and the Howe-Kjeldahl methods, covering a comparatively wide range of globulin values, are given in Table I. As the method here described is essentially one for the estimation of globulin, values for that fraction only are reported. It will be noted that the correlation between the two methods is close, in fact closer than that usually obtained in a series of total protein determinations. This may be explained in part by the fact that variations in serum constituents, such as salt and glucose, which are soluble in the reagents employed, have no appreciable effect on the result. The standard deviation between the two methods is ±0.14 Gm. per 100 c.c.

SUMMARY

A method for the determination of serum globulin and albumin by specific gravity measurements is described.

TABLE I

COMPARISON OF HOWE-KJELDAHL AND SPECIFIC GRAVITY METHODS FOR SERUM GLOBULIN
Values in Gm. per 100 c.c.

SPECIMEN	HOWE-KJELDAHL	SPECIFIC GRAVITY	SPECIMEN	HOWE-KJELDAHL	SPECIFIC GRAVITY
1	1.7	1.7	13	2.2	2.2
2	3.2	3.1	14	5.1	5.1
3	3.8	3.7	15	1.7	2.0
4	2.1	2.2	16	1.8	1.6
5	4.3	4.0	17	3.0	3.1
6	2.4	2.5	18	1.9	2.0
7	4.3	4.3	19	4.1	4.1
8	3.6	3.6	20	4.9	4.8
9	3.7	4.0	21	5.6	5.6
10	3.7	3.8	22	1.5	1.5
11	2.3	2.3	23	2.7	2.5
12	1.5	1.3	24	2.5	2.5

The globulin is determined by precipitation with one-half saturation of ammonium sulfate, the precipitate being subsequently treated with 5 per cent trichloroacetic acid and redissolved in 2.25 per cent sodium hydroxide. The difference between the specific gravity of the resulting solution and that of a blank prepared from the trichloroacetic acid supernatant liquid represents the amount of protein in the solution, and when used in conjunction with the total protein value gives a basis for calculating both the albumin and globulin fractions.

Any specific gravity method suitable for estimating total serum protein may be employed, and no additional standard is required.

A comparison of the results with those of the Howe-Kjeldahl method is given.

CLINICAL AND EXPERIMENTAL

ON THE ABSORPTION AND EXCRETION OF METHYLSALICYLATE ADMINISTERED BY INUNCTION*

R. BEUTNER, M.D., PH.D., B. CALESNICK, M.S., E. POWELL, B.A., AND L. BORTIN, B.A., PHILADELPHIA, PA.

PREVIOUS RESEARCH

THE percutaneous absorption of the salicylates, including methylsalicylate, was investigated as early as 1876 by Drasche,[3] who showed that an alcoholic solution of salicylic acid applied to the skin caused an almost immediate appearance of salicylate in the urine. Since then, numerous other investigators[1, 7] have confirmed the rapid percutaneous absorption of salicylic acid. As this drug proved too irritant for inunction, further attention turned to its esters. Several of these were found to be more rapidly absorbed from the skin, such as methyloxymethyl salicylate, glycol salicylate, and particularly the now preferred methylsalicylate (Impens and Sauerland).[6, 8] In some quarters, however, the percutaneous absorption of the methyl ester is still doubted. Goodman and Gilman,[4] for example, propound the following judgment:

> "Methylsalicylate is . . . absorbed when applied cutaneously, but this route is too uncertain when systemic effects are desired."

There may be some justification for such criticism, as the evidence assembled so far has not been convincing. To wit: Sauerland[8] found that only 0.5 per cent of the applied methylsalicylate was absorbed from the skin, though Impens[6] maintained that the amount absorbed was 8 per cent to 9 per cent; Hanzlik and Preshlo[5] found absorption to be considerably delayed; therefore, they judged it to be slow and irregular; certain other investigations appear unconvincing because of the rather artificial methods of application used, such as the immersion of hands in fatty or alcoholic solutions of methylsalicylate, etc. (Brown and Scott).[2]

*From the Department of Pharmacology, the Hahnemann Medical College and Hospital of Philadelphia.

Received for publication, March 25, 1943.

INVESTIGATION ON A LARGER SCALE

The study here described was done with a larger number of subjects than those reported by previous investigators. A total of 103 inunctions were made on 86 individuals. The series was large enough to lead us to believe that an over-all average may be established in spite of considerable variation from individual to individual, caused by differences in skin permeability, kidney function, etc. The study was undertaken *to determine the salicylate excretion after* inunction of methylsalicylate and to compare it with that occurring after the oral administration of one tablet (0.3 Gm.) of acetylsalicylic acid.

VEHICLES USED

Three different methylsalicylate ointments were used in the study. While their salicylate content was the same (20 per cent), different bases were employed as vehicles:

1. Anhydrous lanolin
2. Anhydrous lanolin and menthol, giving the ointment the following composition:

Lanolin	60 per cent
Menthol	20 per cent
Methylsalicylate	20 per cent

3. A special aqueous base containing:

Glycerin monosterecate	35.0 per cent
Phenolic resin	4.2 per cent
Acacia	3.5 per cent
Water	28.0 per cent
Alcohol	28.0 per cent
Glycerin	1.3 per cent
Total	100 per cent

This rather solid mixture of base 3 was able to emulsify 20 per cent of its weight of methylsalicylate and 20 per cent of menthol, forming a soft ointment which upon inunction was absorbed by the skin without leaving the skin greasy. The lanolin ointments, by contrast, leave a greasy residue, no matter how long they are rubbed on the skin.

As the presented observations will show, the type of ointment used exerted little influence upon the amount of methylsalicylate absorbed. The amount of ointment used for each inunction, regardless of base, was 10 Gm.

TIME LIMITS OF EXCRETIONS

In order to determine the time over which salicylate is excreted, as well after inunction of methylsalicylate as after oral administration of acetylsalicylic acid, urine samples were collected at short intervals after inunction or ingestion, viz., after ¼ hour, ½ hour, 1 hour, and 2, 4, 8, 12, 18, 24 hours. Each sample was tested qualitatively for the presence of salicylate by the addition of a ferric salt; if the urine sample had to be acidified, a small amount of hydrochloric acid was added.

Eight subjects were used for this qualitative determination with methylsalicylate inunctions. In two of these, excretion was limited to two hours; in five, it occurred over a period of 12 hours; only in one case was excretion protracted more than 12 hours.

With acetylsalicylic acid taken by mouth 33 subjects were used. In 31 of these, salicylate excretion was completed in 12 hours; in the other two, a small residual amount was excreted a few hours later.

For the purpose of determining quantitative excretion it seemed justified therefore to limit the time, over which the urine was to be collected to 12 hours.

QUANTITATIVE DETERMINATION

The subjects employed were medical students whose interest in the study assured the proper carrying out of instructions. Each of the subjects was routinely provided with 10 Gm. of a 20 per cent methylsalicylate ointment and instructed to rub the ointment into the skin of his chest, abdomen, and thigh at 6 P.M. without wasting any part of the ointment. If the skin felt uncomfortably greasy after inunction with the lanolin ointments, the excess could be wiped off one-half hour after application, but not sooner.

TABLE I

AMOUNT OF SALICYLIC ACID (IN MG.) EXCRETED AFTER INUNCTION WITH 2 GM. OF METHYLSALICYLATE CONTAINED IN 10 GM. OF AN OINTMENT CONSISTING OF ANHYDROUS LANOLIN 80 PER CENT AND METHYLSALICYLATE 20 PER CENT

NAME	MG. OF SALICYLIC ACID EXCRETED	DEVIATION FROM AVERAGE	VOLUME OF URINE IN 12 HOURS

Average:	41.6	9.3*	

*Average positive deviation: 7.7.
Average negative deviation: 11.5.

All urine voided from the time of the inunction until the next morning was to be collected in a vessel provided for the purpose. At least two voidings were to be made. The total urine so collected was measured, and 100 c.c. of it were used for determining the salicylate content. Determination was made according to the method of Thoburn and Hanzlik, as follows:

The urine (100 c.c.) and 20 c.c. of added syrupy phosphoric acid were boiled in a 500 c.c. Erlenmeyer flask over a direct flame. The flask was connected with an attachment for conducting steam through it and also with a condenser. Steam was run through the flask, and the distillation was continued until a few drops of the distillate failed to give a pink color reaction when 1 or 2 drops of iron ammonium sulfate were added. When the contents of the Erlenmeyer flask, during the process of distillation, were almost exhausted, or when they foamed and gave rise to fog, water was added and the distillation continued until the distillate proved free from salicylate.

Iron ammonium sulfate was added to the distillate until the violet color of the reaction could no longer be intensified by further addition of the ferric salt. Salicylic acid was then determined colorimetrically by checking against a stand-

ard solution containing 0.115 Gm. of sodium salicylate per liter; 1 c.c. of this standard solution corresponds to 0.1 mg. salicylic acid; enough iron ammonium sulfate was added to give the maximal pink color (which remains constant for a week).

The quantity of salicylic acid in the 100 c.c. sample was thus determined and, from it, the total quantity of the acid excreted in the urine after inunction with an

ointment containing 2 Gm. of methylsalicylate. The results obtained are listed in the tables shown.

INFLUENCE OF VEHICLES

The vehicle used to present the salicylate to the integument appeared to be of no influence upon the amount excreted in the urine. For confirmation of this finding a number of innunctions with the different bases were made on the same individuals; again the vehicles appeared to be without significant influence (cf. Table IV). When anhydrous lanolin constituted the vehicle, average excretion was 101.3 mg. of salicylic acid; with the absorbable base, 103.1 mg. were excreted; in both instances menthol (20 per cent) had been added to the ointment. Within the limits of experimental error, these figures (amounts excreted) are obviously identical.

It is interesting to note here that the omission of menthol, when the ointment presented methylsalicylate alone in anhydrous lanolin, resulted in a considerably smaller amount of salicylic acid excreted, an average of 64.6 mg. Apparently the addition of menthol promotes greater absorption, hence greater excretion.

On the whole, all averages in this comparative series of innunctions (made on the same individuals) were higher, because a selected group of subjects was used, men who had shown better cutaneous absorption than the average. Dark-complexioned individuals apparently have a higher absorption ability than the blonds.

The data of urinary excretion after oral administration of acetylsalicylic acid are presented in Table V.

CONCLUSION

Tables I to VI show that the following quantities of salicylic acid were excreted:

From Innunction

	Tables I, II, III mg.	Selected Group Table IV mg.
(a) without menthol in lanolin	41.6	64.6
(b) with menthol in lanolin	55.1	101.3
(c) with menthol in absorbable base	47.5	103.1
Average	48.1	89.7

From Oral Ingestion

acetylsalicylic acid, Table V: 65.8 mg.

It is evident that excretion of salicylate after *oral* administration of acetylsalicylic acid (average 65.8 mg.) is on the same level as that from cutaneously applied methylsalicylate (averages 48.1 to 89.7 mg.). If the excretion is virtually the same, it is only logical that absorption into the blood stream and the systemic influence exerted also must have been the same. The conclusion ap-

Antipyretic Effect of Methylsalicylate Inunction

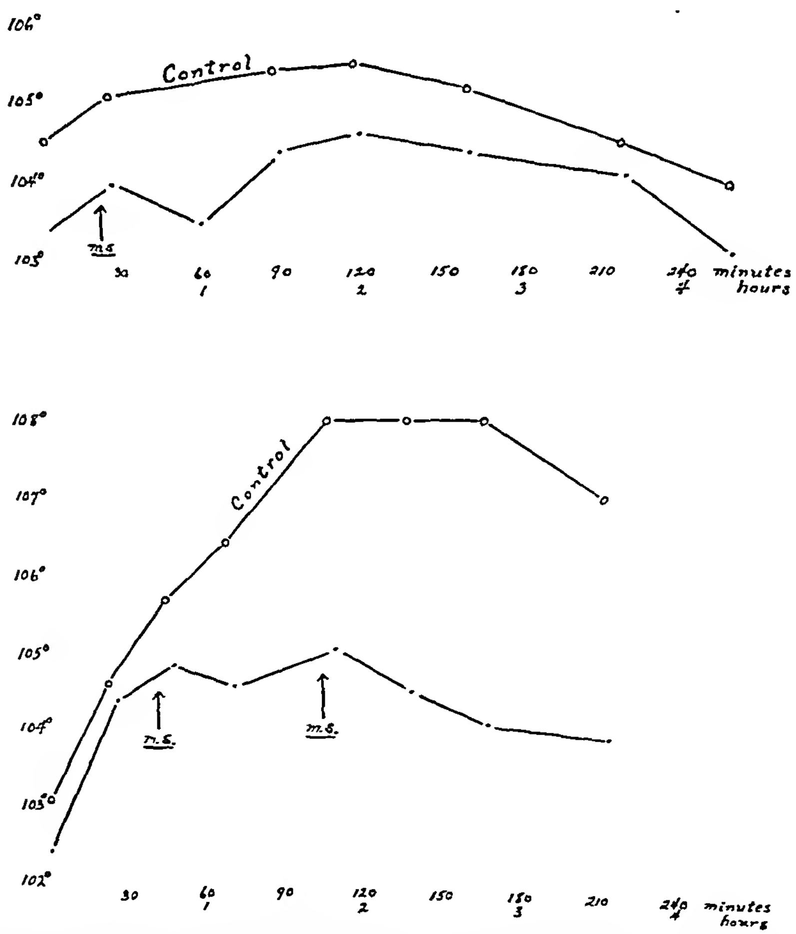

Fig. 1.—In each of these two sets of experiments two rabbits were used; both were injected with 20 mg./kg. of cocaine hydrochloride, whereupon the rectal temperature gradually rose, later slowly returning to normal as indicated. After the application of a 20 per cent methylsalicylate ointment to the ear of one of the animals, however, *m.s.* on graph, a prompt drop of temperature was seen. This drop may be the result of central action of methylsalicylate on the (disturbed) heat center, since we have shown that sizable amounts of this salicylate are absorbed through the skin, or it may be due to a vasodilation resulting from the local irritating effect exerted by the drug. Or both types of action may contribute to the lowering of temperature.

pears justified, therefore, that an adequate inunction of methylsalicylate ointments, of the types described, must be considered internal medication.

ANTIPYRETIC AND VASODILATING EFFECT OF METHYLSALICYLATE

In order to test whether methylsalicylate upon cutaneous application exerts a systemic influence, its antipyretic effect was investigated. Rabbits were injected with cocaine in a quantity of 20 mg. per kilogram of body weight. Within two hours, the temperature of the injected animals gradually rose from approximately 103° F. to approximately 106° F., then slowly returned to normal. When methylsalicylate ointment was rubbed into the ears of the animals, the temperature dropped promptly (see Figs. 1 and 2). This effect may, of course, have been merely the result of the vasodilation produced locally by methylsalicylate, which is a counterirritant.

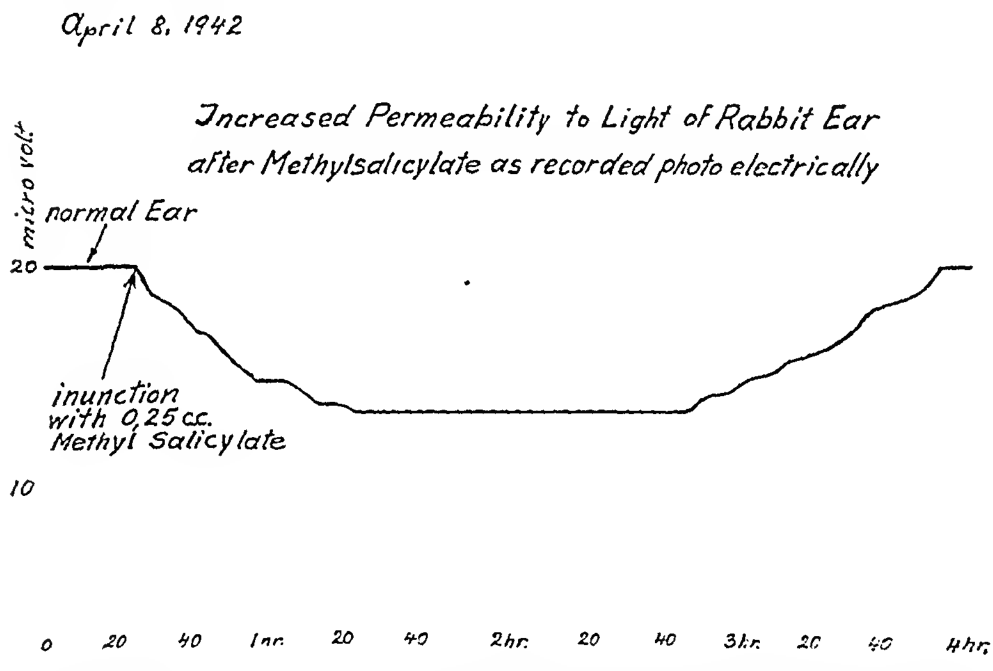

Fig. 2.—The from local application of methylsalicylate on the rabbit's ear was studied ear was held in a frame close to a photoelectric cell (RCA high vacu . The light from a small 3 volt bulb, fed by a 2.5 volt battery was allowed to fall on the rabbit's ear; some of it passed through the translucent tissue and elicited a feeble photoelectric current of the phototube, the voltage of which was recorded continuously on a Leeds and Northrop "Micromax Recorder." The accompanying graph is a twofold magnification of the record thus obtained.

At the point indicated on the graph, the rabbit's ear was rubbed gently with two drops of methylsalicylate, whereupon the photoelectric current decreased due to the greater opaqueness from hyperemia through irritation by the methylsalicylate. Mere mechanical rubbing without a drug had no such effect. (Performed by Mr. George Callé.)

This well-known property of the drug was again demonstrated by the increased ability of a rabbit's ear, after inunction, to transmit light, as measured photoelectrically (see Fig. 2).

SUMMARY

The absorption and excretion of cutaneously applied methylsalicylate was tested in 83 individuals on whom a total of 103 inunctions were made.

Findings were compared with those derived from the oral administration of acetylsalicylic acid.

Similarity of the derived figures (averages) justifies the conclusion that methylsalicylate upon cutaneous application exerts not only its long-established counterirritant influence (vasodilatation, decongestion, induction of active hyperemia), but also a systemic action which perforce must be analgesic, antipyretic, and antirheumatic, since these properties are common to the salicylates upon absorption.

SYSTEMIC ALLERGIC REACTION INDUCED BY YELLOW FEVER VACCINE

HARRY SWARTZ, M.D.*

THIS is the record of a case of severe constitutional reaction to the single immunization injection of yellow fever vaccine. It is not the purpose of the writer to detract in the least from the established value of this most efficacious prophylactic agent. In an exhaustive review of the literature, not a single similar case was discovered. When it is considered that upward of several million immunizing injections of yellow fever vaccine have been given to date, the rarity of the case reported below is obvious. It is undoubtedly true that many such reactions of much less severity have been seen and have gone unrecognized or have been recognized and considered of no importance because of their mildness.

Three cases resembling the writer's in minor aspects have been reported by Sulzberger and Asher.[1] These were cases of urticaria and erythema multiforme-like eruptions appearing thirty-six or more hours after yellow fever vaccine injections. Accompanyng the skin manifestations were arthralgias, malaise, fever, pruritus, nausea, and vomiting. As the authors state, the entire symptom complex simulated serum sickness rather than the immediate constitutional reaction of atopy.

It is the intention of the writer to point out by example the necessity of knowing, generally, the constitution of the material injected and of the patient himself.

*Lieutenant, Medical Corps, U.S.A.
Received for publication, March 30, 1943.

REPORT OF CASE

A 27-year-old white male was admitted to the hospital on October 15, 1942, for observation. About one month before admission, he received a single injection of cholera vaccine and one of yellow fever vaccine. Less than five minutes after these injections, while making his way out of the clinic, he became acutely ill. His vision blurred; his breathing became labored and extremely difficult; nausea, vomiting, diarrhea followed and generalized edema of the skin upon which appeared large, raised, pruritic, erythematous wheals. The dyspnea increased in severity, and in a short time he lost consciousness.

After repeated subcutaneous injections of epinephrine, the patient regained consciousness. He was then hospitalized; the severe dyspnea, angioneurotic edema, urticaria, and the gastrointestinal symptoms continued. Epinephrine subcutaneously and ephedrine sulfate orally were maintained in decreasing frequency for the next six days, at which time all symptoms disappeared. He was then discharged from the hospital.

Two days later, while engaged in strenuous physical activity, he experienced a severe paroxysm of dyspnea which lasted two hours. In milder form, it continued for two weeks accompanied by nocturnal wheezy respiration. He was again hospitalized for four days, during which time bronchial symptoms persisted. In addition, a mild generalized urticaria, bullous in character, was noticed. Symptoms subsided and he was transferred to this hospital.

The past history of this patient is of special significance. At the age of four, he contracted the "flux," during which illness he was fed large quantities of egg and egg white. From that time on, he was unable to eat eggs. His inability was initiated not only by a marked aversion for them, but also by the knowledge that ingestion of the smallest fraction of an egg or egg-containing food would precipitate severe asthmatic paroxysms. These paroxysms, he noticed, would also appear on close contact with feathers, e.g., sleeping on a feather pillow or working in the chicken coops on the farm where he lived. In addition to asthma, eggs in any form and in the minutest quantity produced nausea, vomiting, diarrhea, swelling of the face, arms, legs, and generalized itchy wheals. As he grew older, other foods produced the same variety of symptoms in somewhat lesser degree. Those he was definitely able to indict were chicken, pork, chocolate, and peanut. He also noticed that the asthma which had become an almost constant but mild characteristic of his life was most marked during the fall and winter seasons. (His home was in Tennessee.) About six years ago, the attacks decreased in frequency and severity, appearing only at long intervals.

Five years ago, he received a single injection of a vaccine as protection against "flu." A few minutes later, an episode similar to the one described above followed. It was treated with epinephrine and subsided in several hours. The nature of the vaccine could not be determined.

The family history was essentially negative except for his father who had had asthma since childhood.

Physical examination on October 15, 1942, revealed a well-developed, white male, sixty-nine inches tall, weighing one hundred and sixty-five pounds with no significant abnormal physical signs. The blood picture and chemistry, urinalysis, serology showed no abnormalities. The EKG was normal. X-ray of the sinuses showed clouding of the left frontal; others were normal. X-ray of the lungs and chest wall showed no abnormalities.

The allergy investigation, which was as exhaustive as facilities permitted, revealed interesting findings. No precise laboratory investigations were instituted so that the specific modified responsible allergen could not be determined; however, intradermal tests, direct and indirect (passive transfer), and clinical tests were made. All of these pointed incontrovertibly to a single solution of the problem: what was the agent that produced the severe constitutional reaction in this patient? The writer deems it best for clarity to develop these investigations apart from the body of the case report.

The history of this patient, which immediately labelled him an atopic individual with a multivalent sensitivity including a persistent, marked egg

and chicken sensitivity, presented an almost immediate theoretical answer to the severe, near-fatal constitutional reaction following injection of the two vaccines. Yellow fever vaccine was prepared by inoculating eggs incubated seven to eleven days with the 17-D strain of attenuated yellow fever virus developed by Theiler and Smith. This was followed by three more days of incubation, at which time the still-living embryos were aseptically removed from their shells, whatever albumin attached to the embryo not being disturbed. They were ground to a fine pulp in blenders cooled with dry ice, diluted with normal human serum or distilled water, centrifuged for thirty to sixty minutes in an angle centrifuge at about 3,500 revolutions per minute to remove tissue debris. The supernatant extract constituted the vaccine. This was evaporated at a low temperature, standardized, and kept at 4° C. When needed it was dissolved in ten volumes of sterile distilled water and given immediately in 0.5 c.c. doses subcutaneously.[2, 3]

The patient was tested intradermally to more than one hundred allergens. Many inhalant and ingestant skin sensitivities were found. Especially marked reactions were obtained to egg white, chicken meat, and yellow fever vaccine undiluted (four plus). Yellow fever vaccine diluted 1:10 produced a two plus reaction. Cholera vaccine was negative at the end of ten minutes, twenty-four hours, and forty-eight hours. Thus far, proof had been obtained of specific skin sensitivity which confirmed his history of atopy. Because cholera vaccine gave a negative skin reaction both immediate and delayed and because yellow fever vaccine undiluted and diluted 1:10 gave positive skin reactions of the immediate variety, it was established that: (1) cholera vaccine was in no way involved in the constitutional reaction that eventually brought the patient to this hospital, and (2) yellow fever vaccine was undoubtedly the instigating agent.

Clinical tests with the patient's permission both with and without his knowledge (the latter to rule out psychogenesis of resulting symptoms) were performed under close supervision. Both egg and chicken meat were used. Symptoms were reproduced more marked to egg than to chicken meat, mild in degree, controlled with epinephrine.

Clinical sensitivity having been established, it remained only to determine which fraction of the yellow fever vaccine was responsible for initiation of symptoms, the virus fraction or the culture medium fraction. In order to do this, several c.c. of the patient's serum were prepared for passive transfer. The volunteer subject was tested intradermally with the full complement of allergens (more than one hundred), and was found negative to all. Twenty sites on the subject's arm were sensitized, each with one-tenth c.c. of the patient's serum. Forty-eight hours later, these sites were tested with twenty different allergens. At twenty-four-hour intervals, the sites were tested with different series of twenty allergens, until all of those which had produced positive reactions on the patient's skin were tested in this manner. Most of these gave positive reactions on the sensitized sites to lesser degree. Egg transferred four plus; chicken meat two plus; yellow fever vaccine undiluted two plus; yellow fever vaccine 1:10 one plus. All of these reactions, of course, were of the immediate variety. This demonstrated the evident fact that there existed in the serum of the patient (now in the skin of the subject's arm)

reagins for egg, chicken meat, and yellow fever vaccine. Since a virus is not known to be reaginogenic nor is it known to produce skin reactions of the immediate variety, the obvious deduction follows that it was the culture medium fraction of yellow fever vaccine that called forth reaginogenesis.

It was now left to relate this fraction constitutionally and reaginogenically to either egg white, chicken meat, or both. Three widely separated transfer sites were chosen. These were exhausted of egg reagin by successive reinjection with egg extract until no reaction was obtained. These sites were then tested with chicken meat extract. A positive reaction was obtained. When this had disappeared and an hour had been allowed to elapse, these same sites were tested with yellow fever vaccine undiluted. A slight reaction, less than one plus, resulted.

Three different sites were then chosen, again widely separated. These were exhausted of chicken meat reagin in the same manner as above. The sites were then tested with egg extract; a four plus reaction resulted. When the reaction had subsided, an hour was allowed to elapse and the same sites were tested with yellow fever vaccine undiluted. Positive reactions resulted only slightly less marked than the reactions in the sites where neither egg nor chicken meat reagin had been exhausted.

This is conclusive evidence that the reaginic fraction of yellow fever vaccine is related both to egg white and chicken meat structurally and reaginogenically; that it more closely resembles egg white than it does chicken meat. It is known that, from the point of view of both clinical and skin sensitivity, egg white and chicken meat are totally unrelated. In the embryonic development of the chick from the egg, a mutation and differentiation of egg protein take place. It is conceivable that the reaginic fraction of yellow fever vaccine (chick embryo culture) represents a stage in this mutation and therefore by test reveals a kinship to both egg white and chicken meat, albeit the relationship is closer with egg white.

Berger and Hargett,[3] working on the problem of anaphylaxis in guinea pigs following sensitization with chick embryo yellow fever vaccine and normal chick embryo, state, "Chick embryo protein derived from embryos of different ages possesses the power to produce anaphylactic sensitization in young guinea pigs in direct ratio to the age of the embryos employed. . . . ." If one were to transpose this work in the laboratory to the clinical and investigative observations made in this case, the variance would be seen immediately. According to the above authors, the reaginic fraction of yellow fever vaccine should be more closely related to chicken meat than to egg white. This cannot be borne out by the writer's findings.

COMMENT

The presentation of this case of an egg-chicken meat sensitive atopic individual who experienced a severe constitutional reaction immediately following injection of yellow fever vaccine is made to point out the necessity of knowing something of the constitution of the immunizing injection and the subject to whom it is to be given. This emphasizes, by example, the instructions given medical officers of the army relative to questioning the subject about allergic history before administering a vaccine. It is not meant to detract in the least from the justified use of this prophylactic agent.

Evidence is offered in proof of the reaginicity of yellow fever vaccine culture medium and of its close relationship to egg white and chicken meat, more marked to egg white.

It is suggested that marked sensitivity by history or skin test to egg, chicken meat, or both, and/or by skin test to yellow fever vaccine is an indication to give the vaccine carefully, in divided doses with epinephrine at hand in the event a constitutional reaction occurs.

THE PHARMACOLOGY OF TWO WATER-SOLUBLE VITAMIN K-LIKE SUBSTANCES*

JAMES J. SMITH, M.S., M.D., A. C. IVY, PH.D., M.D., AND R. H. K. FOSTER, PH.D., M.D., CHICAGO, ILL.

THE object of this study was to test the vitamin K activity, general pharmacology, and toxicity of 2-methyl-1,4-naphthohydroquinone diphosphoric acid ester tetrasodium salt $6H_2O$ (N-123)† and 2-methyl-1,4-naphthohydroquinone sodium bisulfite complex (MNSS).‡ A preliminary report of this work was presented at the Chicago meeting of The Federation of American Societies for Experimental Biology and Medicine, 1941.[1] Experiments reported here were carried out in the laboratories of Northwestern University and Hoffmann-La Roche and the separate results are designated NU and HLR, respectively. This distinction is made on account of the slightly varying methods and results of the two laboratories.

I. VITAMIN K ACTIVITY

Tests were made on hypoprothrombinemic rats by (a) "Petrolagar" diet;[2] (b) Bile duct obstruction after a preliminary depletion with a diet of low vitamin K content.[3, 4] After depletion, the prothrombin deficient rats were treated with subcutaneous injections of N-123 and MNSS.

METHODS

Production of Deficiency (NU).—Petrolagar diet.—Ninety stock rats weighing from 110 to 230 Gm. were placed on a diet consisting of 70 per cent

*From the Departments of Physiology, Northwestern University Medical School, Chicago, and the Scientific Department, Hoffmann-La Roche, Inc., Nutley, N. J.

Received for publication, March 30, 1943.

†Synkayvite, Hoffmann-La Roche, Inc.

‡Hykinone, Abbott Laboratories, Inc. This substance is an addition product rather than the -3-sodium sulfonate originally reported.[11]

powdered Purina Dog Checkers and 30 per cent Petrolagar. Significant hypoprothrombinemia* developed in 25 per cent of surviving rats in 8 to 96 days as shown by the Quick prothrombin time method.[6] Thirty-two of these rats died in the course of an epidemic of infectious middle ear disease, which swept the colony 30 days after beginning the diet. Thirty-five additional rats were then placed on the diet for a shorter period; of these approximately 50 per cent showed a prolongation of prothrombin time to double or more the original value within 38 days. *Biliary obstruction:* Forty rats were placed on a diet low in vitamin K[5] for periods ranging from 32 to 44 days. In 32 of these the common bile duct was doubly ligated and cut under ether anesthesia. Of 23 rats surviving repeated cardiac puncture and biliary obstruction, 9 or 39 per cent showed a marked hypoprothrombinemia 3 to 10 days following ligation of the common bile duct. During the dietary period there were no significant changes in prothrombin times.

Production† of Deficiency (HLR).—Oil and Oil-Agar Diets.—Petrolagar and later Afkol (a similar preparation) were used, mixing 30 per cent in powdered Purina Dog Chow. Also, 20 per cent mineral oil in the Purina food was used since it kept better and did not mold. Since only a few rats developed significant hypoprothrombinemia, the diet method was abandoned. *Biliary obstruction:* The bile duct was doubly ligated and sectioned. Rats previously on the oil or oil-agar and Purina diet for two months or longer developed prothrombin deficiency in 8 or 10 days. Rats placed on the diet only after operation required 2 to 3 weeks to develop the deficiency. All animals were continued on the diet postoperatively. Seventy-two rats were successfully operated. Of these, 28 died within 2 or 3 weeks though none within the first day or so. Thirty-one deficient rats died following cardiac puncture.

Prothrombin Determination.—Under ether anesthesia 0.45 c.c. of blood was obtained by cardiac puncture (27 gage needle) and drawn into 0.05 c.c. of sodium oxalate solution (1.34 per cent); to this was added 0.5 c.c. physiologic saline, and the specimen was centrifuged. The coagulation time of the plasma was determined by a modified Quick method.[6] To 0.1 c.c. of oxalated plasma at 38° C., 0.1 c.c. of thromboplastin‡ (Quick[7]) was added and quickly thereafter 0.1 c.c. of calcium chloride solution (0.27 per cent). Clotting time was noted with a stopwatch and at least two determinations were run on each sample.

Method of Treatment (NU).—When the prothrombin time had increased significantly (at least twice original value) the animals were injected subcutaneously for two days or more with 2 and 4 gamma doses of both compounds. Prothrombin time (PT) was determined daily. Control animals were injected with physiologic saline, and both substances were dissolved in saline and injected in volumes of 0.5 or 1.0 c.c.

Method of Treatment (HLR).—Depleted animals were injected with single doses ranging from ¼ gamma to 2 gamma per rat. Prothrombin times were determined 18 to 20 hours later. Since the HLR results are reported in terms of per cent prothrombin, a curve relating prothrombin time to per cent pro-

*Prothrombin time increased to twice or more the original level.

thrombin was determined by plotting data obtained from tests on serial dilutions of plasmas from five normal rats, following the method of Quick.[6]

RESULTS

Results (NU).—Controls.—The mean control reading of prothrombin time in 144 normal rats (both on dietary rats and bile duct obstructed rats) was 22.9 seconds ±0.16 second (S. E. of mean) of ±1.9 seconds (S. D.).

Table I shows the daily PT determinations of 13 rats receiving 0.5 or 1 c.c.

**P = Prothrombin Time in seconds.

injections of physiologic saline. It is seen that the PT shows rather marked variations from day to day, and in three cases, rats B_3, P_2 and P_9, the injection of saline was accompanied by a considerable reduction of the prothrombin time. Such remissions are thought to be fortuitous and perhaps explainable on daily variations in intestinal absorption. Also, small variations in the vitamin K absorbed are likely to produce magnified changes in prothrombin time when the blood prothrombin level is low, because of the steep slope of the prothrombin time/per cent prothrombin curve in this region. Statistical analysis, however, reveals no significant differences between the mean values for successive days in this control series.

Treated.—In Table II are listed the responses to daily subcutaneous injections of 4 gamma of N-123. The critical ratio ("Student's" "t") between PT before injection and 24 hours after the first injection is 5.03 and between PT before injection and 24 hours after the second injection is 6.32, thus being in both instances highly significant ($P < 0.0002$).

In Table II are shown the responses to subcutaneous injections of 4 gamma MNSS. The critical ratio of the mean PT before injection and after injection is very high (over 6). The critical ratio between the mean value after the first injection and the mean after the second injection is 1.50 (or $P = 0.15$), so most

of the effect of vitamin K was obtained in the first 24 hours. Also in Table II is shown the response of the PT to 2 gamma doses of N-123 and MNSS, respectively.

Storage of Vitamin K in the Body (NU).—In the course of our study, 15 PT determinations were made on 12 rats at various times *after* the deficiency had already been corrected with a series of injections. The results are shown in Table III.

The results show that when the prothrombin time is brought nearly to normal, at 5 days after the last injection it is practically back to the deficient level. These animals received doses of the vitamin K preparations totaling 8 gamma in most cases.

Results (HLR).—The mean of 39 PT determinations on normal rats was 21.8 seconds ±0.4 second (S.E. of mean). The standard deviation of a single observation was ±2.5 seconds. These values check well with the NU values.

Injections of N-123 and MNSS were made subcutaneously in deficient rats weighing 150 to 200 grams and PT tests made 18 to 20 hours later. The doses ranged from ¼ to 2 gamma per rat. All deficient rats were markedly jaundiced

and their plasmas were yellow. The results in terms of per cent prothrombin are shown in Table IV. With doses of 2 gamma there was a tendency for the PT to return to a level below 21.8 seconds; that is, the *calculated* per cent prothrombin became higher than normal. This phenomenon does not occur in vitamin K-treated normal animals, however.

When the data are graphed (Fig. 1), it may be noted that with higher doses the two curves approach each other, but that in the lower range there is greater divergence. Doses have been estimated from the curves which give specific effects and these are tabulated in Table V. In addition the relative potencies by weight and molecular weight are given in the latter table. The data in this table demonstrate that on a molecular basis N-123 is 41 per cent more potent than MNSS although on a weight basis it is 26 per cent less potent. These data indicate by indirect comparison that MNSS and 2-methyl-1,4-naphthoquinone (MeNQ) have about equal molecular potencies, since Lee et al.,[8] and Almquist and Klose,[10] respectively, reported N-123 to be 48 per cent and 51 per cent more potent on a molecular basis than MeNQ.

50	1.34	1.10	0.82	1.58
	Average		0.74	1.41

On the Mechanism of Vitamin K Action.—While it is now accepted that vitamin K acts by stimulating the production of prothrombin in the liver, the possibility suggested itself, especially earlier, that there might be a direct action in the blood. Particularly because of the greater molecular potency of N-123 over all known vitamin K-like substances, it was deemed advisable to perform some tests in vitro.

Deficient rats whose prothrombin times varied from 30 to 43 seconds were used. Oxalated whole blood and oxalated plasma were obtained and incubated at 37° C. for ½ to 6 hours with amounts of N-123 varying from 0.1 gamma to 10 gamma per 0.1 c.c. Then the regular prothrombin determinations were made. There were no significant changes in the prothrombin time with either

plasma or whole blood. This observation was confirmed, using blood from 2 patients with hypoprothrombinemia and jaundice.

DISCUSSION

These results indicate that both water-soluble substances are capable of correcting prothrombin deficiencies in rats at dose levels of 2 to 4 gamma per day. At these dose levels the results in the Northwestern University laboratory indicated no significant difference between the two compounds (Table II). Since the ratio of their molecular weights is 530:276, this would indicate that N-123 is about twice as potent as MNSS on a molecular basis; however, the data from the Hoffmann-La Roche laboratory indicated only 50 per cent greater potency by molecular weight.

Since it has been established[8, 10] that the molecular ratio of potency, N-123:MeNQ is about 1.50, it follows from Table V that the molecular ratio of potency, MNSS:MeNQ is 1.50:1.41 or 1.06. While this indirect comparison is only an approximation, it suggests that MNSS and MeNQ are probably of about equal potency on a molecular weight basis.

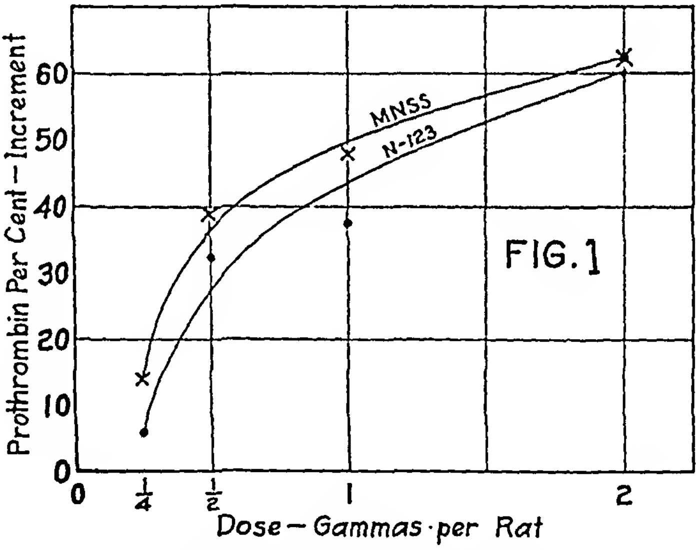

Fig. 1.—Dose-effect curves for N-123 (●) and MNSS (×). Ordinate represents the rise in per cent prothrombin, not the actual per cent prothrombin.

The above ratio, N-123:MeNQ = 1.50, is based on chick assays (both oral feeding and subcutaneous injection). The activity of MeNQ on rats was studied by Flynn and Warner[3] who gave 2 gamma MeNQ daily for two days to bile duct obstructed rats and raised the prothrombin level from 10 to 82 per cent. While the indirect comparisons of parallel results in different laboratories is perhaps equivocal, the Flynn and Warner result is roughly comparable to that of the 2 gamma dose of the two water-soluble substances in Table IV or to the 4 gamma dose in Table II. Taking the latter as the least favorable of the two comparisons, the potency ratio for rats, N-123:MeNQ, is still 1:2 by weight or about 1.54 by molecular weight. This remains to be verified by direct comparison.

II. TOXICOLOGY AND PHARMACOLOGY

Acute Toxicity (NU).—Acute lethal doses were determined by single dorsal subcutaneous injections in albino rats. The animals weighed from 155 to 310 Gm. and there were a few more female than male rats. The results are shown in Table VI. By plotting these data on logarithmic probability paper the LD50's were found to be 610 mg./kg. for N-123 and 175 for MNSS. The ratio, N-123:MNSS, of doses by weight is 3.48, but on a molecular basis (N-123 = 530 and MNSS = 276) the ratio of lethal doses is 1.82.

In a previous communication by one of us[9] the LD50 for N-123 was reported to be 450 mg./kg. in mice by subcutaneous administration and 675 mg./kg. in chicks by the same route.

TABLE VI

TOXICITY BY SUBCUTANEOUS INJECTION IN RATS (NU)

SUBSTANCE	DOSE MG./KG.	N	PER CENT MORTALITY
N-123	450	10	20
N-123	550	10	30
N-123	650	10	60
MNSS	100	10	0
MNSS	150	10	40
MNSS	200	10	60
MNSS	300	5	100

Symptoms appearing in the rat were similar for both drugs and consisted chiefly in a depression of spontaneous activity and some increase in respiration. The depression of activity was noted principally with doses of 550 and 650 mg./kg. for N-123, and with 150, 200 and 300 mg./kg. doses of MNSS. Symptoms appeared 15 to 30 minutes after injection and continued for several hours after which there was a gradual recovery or a progression to death. No convulsions or hyperactivity were seen at any time. Occasionally there was a temporary paresis of the muscles of one forefoot, especially when the injected material extended to the region of the pectoral girdle. These symptoms were of the general order previously described by one of us[9] for other species, except that, particularly in rabbits, the depressive phase was preceded by some movement and agitation and apparent apprehension. These injections were intravenous, however, and in one case (rabbit 324) a convulsion occurred after 30 minutes, the animal dying 5 minutes later. It is of interest that the convulsion occurred during prostration.

With N-123, death occurred in rats in 12 to 70 hours (average = 30 hours), and with MNSS, in 18 to 140 hours (average = 48 hours). The autopsy findings were essentially the same for both drugs. The most constant findings were a bloody nasal discharge, bloody urine, small petechial hemorrhages in the lungs, and moderate enlargement and congestion of the spleen. With MNSS, the heart was frequently stopped in systole, and in these cases there was marked dilatation of both auricles and of the great veins. Microscopic appearances were the same for both drugs, namely, a few cases of marked degeneration of the lining cells of convoluted and collecting tubules of the *kidney* with accumulation of large amounts of protein material in the lumina of the tubules. In

one animal with N-123, the degeneration had progressed to a scattered necrosis of the tubular walls. Glomeruli and blood vessels appeared normal, and there were no significant changes in the liver or adrenals. At the site of injection there was usually moderate congestion of the blood vessels of the subcutaneous tissue but no necrosis.

Chronic Toxicity.—Rats were injected daily subcutaneously with varying doses of the two substances. These data (NU) are given in Table VII. Throughout the injection period, Groups VI, VII, VIII, and IX seemed somewhat more listless than normal. The animals of these groups all showed a loss of weight which was probably significant, especially when contrasted to the Control Group IV which gained in weight. On the contrary, the animals of Groups II and III, receiving only 5 mg./kg. of the two drugs, gained in weight to a greater extent than their control, Group I. While their gain in weight is significant, it is obviously not significantly greater than the gain in the control group, even though the gain of the control group is itself not statistically significant with certainty.

TABLE VII

EFFECT OF CHRONIC ADMINISTRATION ON BODY WEIGHT OF RATS

GROUP	SUBSTANCE	DAILY DOSE MG./KG.	N	NO. OF DOSES	MEAN BODY WEIGHT BEFORE	MEAN BODY WEIGHT AFTER	MEAN BODY WEIGHT PER CENT CHANGE	P
I	Controls	-	10	-	217.9	237.9	+ 9.6	0.085
II	N-123	5	10	20	199.6	226.2	+13.3	0.037
III	MNSS	5	10	20	212.1	239.3	+12.8	0.013
IV	Controls	-	9	-	202.7	214.9	+ 6.0	
V	N-123	25	4	18	221.3	220.7	- 0.3	
VI	N-123	50	4	18	218.5	194.7	-10.9

VIII	MNSS	25	2	16*	209.0	194.5	- 7.0	
IX	MNSS	50	2	16*	208.0	186.5	-10.3	

*Injections not given on 6th and 7th days because of temporary lack of material.

In Table VIII the data (HLR) from a different series of experiments are given. These animals (mice, rats, and rabbits) were injected for pigmentation studies (see section entitled "Pigmentation"). Injections of N-123 only were made 5 days a week for 4 weeks. The results differed from the preceding in that the animals tolerated much higher daily doses; the 2 days' rest per week from the chemical may explain the difference. None of the mice or rats showed loss of weight up to 300 and 200 mg./kg. daily, respectively. Rabbits developed loss of weight at 200 mg./kg. In this table are also given data on three rabbits injected with methylnaphthoquinone. The loss of weight at a dose of 65 mg./kg. daily was not great, but the question of absorption is present since the material was suspended in polyvinyl alcohol. The dose of 65 mg. is equivalent on a molecular basis to 200 mg. of N-123. In another series of rats injected with N-123 for histopathologic studies all animals without exception gained in weight, the highest dose being 100 mg./kg. for ten doses.

In the series of rabbits injected for hematologic studies there was no significant loss of weight unless the dose was high enough to produce anemia, and even then the results were irregular. In rabbit 357, which received N-123 in 100 mg./kg. daily for 20 doses (5 doses weekly), there was no loss of weight and only a minor slowing up of the rate of growth, even though a moderate

anemia developed. In rabbit 350, which served as a control for 9 weeks and then received four 150 mg./kg. doses, there was a slight loss of weight which developed mostly after cessation of injections, and full recovery from anemia, the loss and recovery paralleling the changes in the red cell count. The anemia in this animal was severe, the red blood cells falling to 1.31 million.

TABLE VIII

PIGMENTATION TESTS WITH N-123 AND MeNQ

Five doses given per week for 4 weeks. Doses were subcutaneous except those starred* which were oral. All but the last three rabbits were treated with N-123.

SPECIES AND NO.	DOSE MG./KG.	INITIAL WEIGHT GRAMS	FINAL WEIGHT GRAMS	PER CENT CHANGE	PIGMENTATION
Mouse 1	100	23	24.7	+ 7	None.
Mouse 2	100	21	23.4	+11	None, died 5 weeks later.

The following tests were with MeNQ:					
Rabbit 411	32.5	2.14	2.67	+16	Trace after 1 week over haunches.
Rabbit 370	32.5*	4.20	4.22†	0	None.
Rabbit 371	65*	3.93	3.73†	− 5	None.

†Weight at 3 weeks.

Pigmentation.—The rats in groups VI, VII, VIII, and IX of Table VII developed a peculiar yellowish-brown pigmentation of the hair, which became evident toward the end of the injection period and deepened in the next one to three weeks after the injections were terminated. From then on there was no apparent change in intensity during 10 weeks of observation. The pigmentation, present chiefly in the hair over the face, back, and thorax, was scattered,

but sharply defined, and tended to be symmetrical. This pigmentation has previously been reported by us.[1] This phenomenon was observed in all rats on the higher doses of the two substances in both the Northwestern University and Hoffmann-La Roche laboratories. In addition, rabbits and mice in the latter laboratory were observed to develop the pigmentation (see Table VIII). All rats and nearly all rabbits with sufficient dosage developed it, but mice were less prone to show the color. The color was similar in the three species and always in discrete patches and nearly symmetrical. In all animals the color persisted for months, but finally disappeared. In one rabbit there was only slight fading after six months.

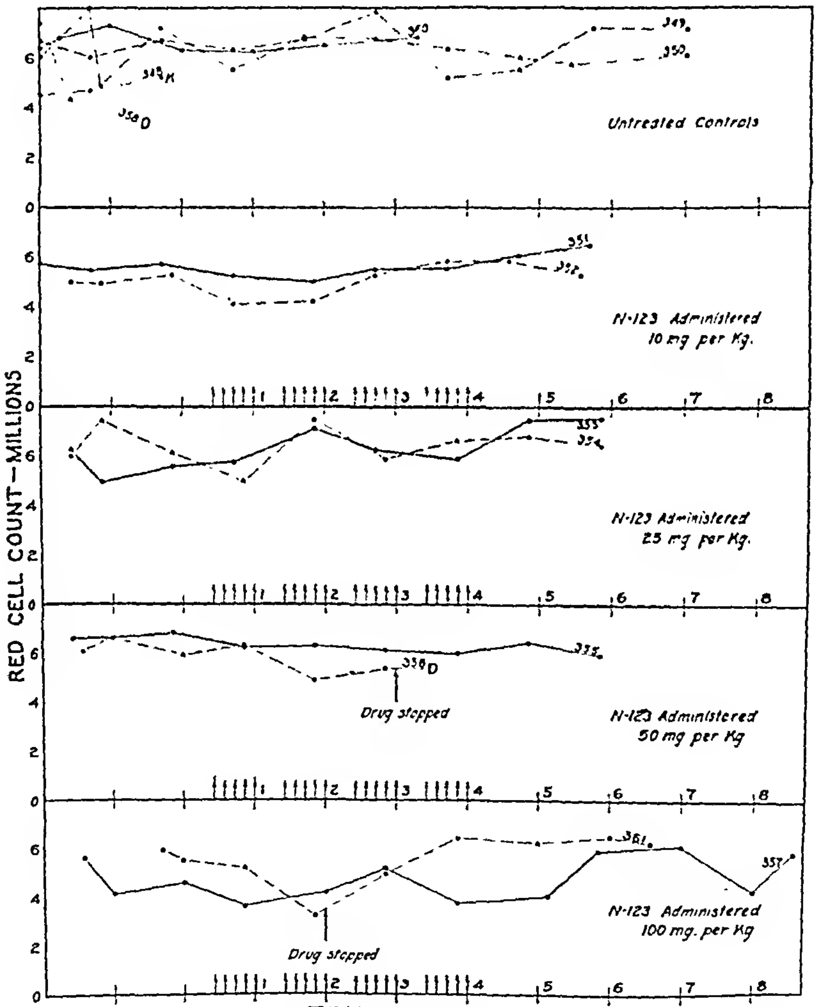

Fig. 2A.—Effect of repeated low doses of N-123 on the red cell count. Arrows indicate the daily injections. D = died.

When N-123 was given orally to rabbits, pigmentation did not occur. Methylnaphthoquinone administered subcutaneously in 3 per cent polyvinyl alcohol solution caused slight pigmentation in one of two rabbits which received 32.5 mg./kg. daily for 20 doses (during 4 weeks). This dose is equivalent to

100 mg./kg. of N-123. At twice the dose administered to one rabbit pigmentation did not occur. There is, of course, the question of absorption here. The MeNQ may possibly have been largely metabolized before absorption. Because MeNQ is irritating there occurred, at the site of nearly every injection, induration which persisted indefinitely, and later a few developed necrosis. The fact that coloring did develop in one rabbit indicates that the phenomenon has its origin in the methylnaphthoquinone nucleus itself, and that the phosphate or sulfonate gives greater effects only because of enhanced solubility. The mechanism of the color production can only be guessed at. A strong solution of N-123 applied daily to the hair had no effect. The color may be due to melanin formation directly or indirectly through metabolic changes in immature hair cells. Possibly vitamins are a factor. The symmetrical and discrete distribution suggests relationship to the color patterns of piebald animals or of nerve and vascular supply.

All rats were colorless after five months. The pigmented rabbits of this series cleared up somewhat faster than previous rabbits in the hematology experiment series.

Micropathology.—Sections from the livers, kidneys, and adrenal glands of the rats in Groups I, II, and III (Table VII) revealed no changes. The doses of N-123 and MNSS were small, 5 mg./kg.

In another experiment on rats (HLR), series of one, five, and ten injections of N-123 were given in 20 and 100 mg./kg. doses. Animals were killed the day after the single dose and three days after the last dose in the other two series. There were no significant changes in the livers or kidneys of any of these animals.

Some of the rabbits under hematologic study were examined. Two rabbits showed no significant gross or microscopic changes after N-123, given subcutaneously in 4 daily doses, 150 mg./kg. One of these animals (No. 349) was killed and autopsied when the red cell count was 1,570,000. The other rabbit (No. 364) was autopsied immediately after death following a convulsion. The convulsion was two days after the last injection, and the red cell count was 1,160,000 on the day of death. Two other rabbits died following similar doses, and delayed autopsy revealed little not attributable to post-mortem changes.

Hematology (HLR).—Eighteen rabbits were started, five serving as controls. Three of the latter were placed in the treated group after several weeks. Coccidiosis appeared in the colony, and one treated (No. 356) and one control animal (No. 358) died. Another control (No. 348) was killed because of severe diarrhea. Aside from these animals, coccidiosis was either mild or did not attack the other animals. N-123 was given daily in doses ranging from 10 to 200 mg./kg. Pronounced effects appeared with doses higher than 100 mg./kg., rabbits receiving the highest doses developing a severe aplastic anemia. Some died, and others recovered following withdrawal of the drug. One animal, No. 350, recovered even though the red blood cells dropped to 1.31 million on the third day after the 4th injection of 150 mg./kg. Following recovery the animals regained normal levels. The red cell counts taken weekly are illustrated in Figs. 2a and 2b. Rabbit 361 showed a drop in red blood cells to 2.90 million after ten 100 mg./kg. doses, but promptly recovered when injections

were stopped. Rabbit 357 actually showed a rise during the first three weeks of injections. Rabbit 360 was injected with 130 mg./kg. a week after the last of four 150 mg./kg. doses. As seen in Fig. 2b there was a temporary relapse after which recovery continued.

Observations were made also on white blood cells and hemoglobin. There were no significant changes except with the highest doses accompanied by severe anemia. In these animals there was usually a polymorphonuclear leucocytosis, but little effect was noted on the eosinophils, basophils, or monocytes. The white cell picture became normal with recovery from the anemia.

Effect on Blood Pressure and Respiration (NU).—Five dogs were used and were anesthetized with sodium pentobarbital. The carotid blood pressure was recorded on a kymograph tracing, and a simultaneous record of respiration was made by means of a pneumograph and tambour. All injections were made intravenously at a rate of 1 c.c. per 3 seconds.

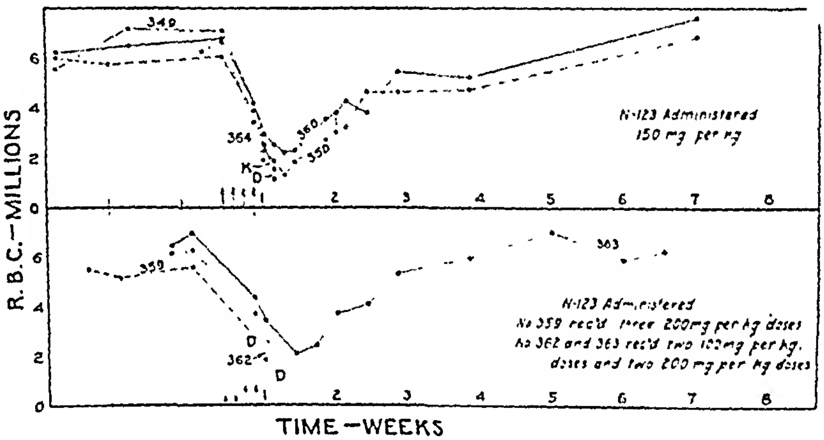

Fig. 2B.—Effect of repeated high doses of N-123 on the red cell count. Arrows indicate daily injections. Half-length arrows indicate a half-size dose in two of the rabbits. Total dose = 600 mg./kg. in all cases, except rabbit 360, which received an additional dose of 130 mg./kg., indicated by the vertical line at second week.

With doses of 20 mg./kg. of either substance, no significant alteration in blood pressure occurred. With 30 mg./kg. of N-123 an elevation in blood pressure began 1 to 2 minutes after the start of the injection, reaching a peak in about 4 minutes and declining gradually to normal in 5 to 10 minutes. No significant secondary increase or decrease occurred. The maximum elevation of arterial pressure was 40 mm. Hg. During this period there was a somewhat decreased respiratory rate. With MNSS 30 mg./kg. resulted in some cases in a transitory slight fall with increased depth of respiration and in other cases no significant changes in either arterial pressure or respiration.

Forty mg./kg. of N-123 caused in one dog a rise in blood pressure of 70 mm. Hg and a greatly increased respiratory rate which was accompanied by a violent stirring about of the animal and an awakening from anesthesia. After 15 seconds, during which time there was no abatement of symptoms, a deeper anesthesia was induced and recovery followed. Similar effects were obtained in cats[9] with 10 mg./kg. doses of N-123 under ether or alurate anesthesia, but the blood pressure reaction was somewhat less under ether. N-123

had little effect on respiration in morphinized rabbits until high doses were given, in which case respiration was depressed.

SUMMARY

1. Two compounds, tetrasodium 2-methyl-1, 4-naphthohydroquinone diphosphoric acid ester $\cdot 6H_2O$ (N-123) and 2-methyl-1, 4-naphthohydroquinone sodium bisulphite complex (MNSS) were studied for vitamin K activity and pharmacologic effects.

2. In bile duct obstructed rats or rats made deficient in prothrombin by dietary means (30 per cent petrolagar in powdered Purina dog chow) 2 to 4 gamma per rat caused a significant shortening of the prothrombin clotting time (Quick method). In one series, 2 gamma of either substance caused the prothrombin time to return to normal and ¼ gamma appeared to be the threshold dose.

3. After the prothrombin time is brought back to normal by the administration of the therapy (about 8 gamma) and then the therapy is stopped, the prothrombin time returns practically to the deficiency level in 5 days.

4. It was shown that vitamin K does not affect prothrombin time on being added to the blood of patients or rats with a prothrombin deficiency.

5. Weight for weight MNSS appeared to be slightly more active, but on a molecular basis N-123 was about 40 per cent more potent.

6. The higher molecular activity of the diphosphate than either MNSS or methylnaphthoquinone is not due to any direct action on the blood in vitro.

7. The LD50 in rats for N-123 is 610 mg./kg. and for MNSS is 175 mg./kg. by subcutaneous injection.

8. In rats receiving high doses of either drug, there was a lowering of spontaneous activity and an increase in respiration.

9. In dogs under pentobarbital anesthesia doses of 30 to 40 mg./kg. caused a marked rise in pressure and respiratory stimulation. MNSS did not exhibit these effects.

10. Lethal doses with both drugs administered to rats resulted in gross and microscopic changes, especially general petechial hemorrhages and renal degeneration.

11. The chronic administration of 100 mg./kg. of N-123 in rats resulted in no pathologic changes.

12. In rabbits, doses of N-123 above 100 mg./kg. caused an "aplastic" anemia from which complete recovery occurred in some animals; others died. Those dying showed no significant microscopic changes directly attributable to the substance. Except for a transient polymorphonuclear leucocytosis during the aplastic anemia there were no significant changes in animals recovering.

13. Mice, rabbits, and rats all developed a yellow to orange-brown pigmentation of the fur in from one to three weeks following a series of medium to large doses of either substance. This pigmentation remained for months with but slow fading. Mice were the least susceptible to the pigmentation phenomenon.

14. The margin of safety between the therapeutically effective and toxic dose of the two preparations is relatively enormous.

THE EFFECTS OF VITAMIN B DEPRIVATION ON SPONTANEOUS ACTIVITY OF THE RAT*

A. L. Bloomfield, M.D., and M. L. Tainter, M.D.
San Francisco, Calif.

THE effect of vitamin deficiency on activity is not only of biologic interest, but in time of war, when food supplies are short, it is also a matter of great practical moment. There is a general impression among clinicians that deficiency of the Vitamin B complex results in fatigue and sluggishness both mental and physical; this impression has recently been supported by certain purposeful studies. Williams and his associates in 1940 found that women placed on a diet extremely low in thiamine developed inactivity and apathy in addition to loss of weight and prostration. In a later study (1942), in which the thiamine deprivation was less extreme, they also found "physical inefficiency." There were no quantitative measurements. O'Shea, Elsom, and Higbe (1942), however, detected no deterioration in the speed of hand muscle coordination when subjects were deficient in the B vitamins and no improve-

Received for publication, March 30, 1943.

ment after therapy with Vitamin B. Williams and Mason (1942) produced no noticeable symptoms in people placed for six months on a diet supposed to be deficient in riboflavin. Simonson, Baer, and Enzer (1942) made the interesting observation that excessive intake of the Vitamin B complex did not affect ability to perform five different types of muscular work, but the treated subjects felt a subjective improvement of working capacity. Finally Keys and Henschel (1942) showed that additions of vitamins to the standard ration did not improve the physical performance of men in the army.

From the laboratory standpoint Guerrant and Dutcher (1940) found that young rats (23 to 26 days old) placed on a diet deficient in the B complex but supplemented with riboflavin and a rice polish concentrate, so that the food was presumably deficient only in thiamine, were more active for a period of three to four weeks than controls which received thiamine supplements. As the effects of vitamin depletion became severe, activity fell off but increased again when Vitamin B_1 was added to the diet.

Because of the indefinite, and indeed contradictory, character of some of the results in the above reports, it seemed useful to attempt further measurements of the spontaneous activity of rats on deficient diets. The present paper deals with this problem.

METHODS

There is a huge literature on measurement of the activity of the rat under various conditions. Briefly, for our present purpose, it may be said that female white rats, when placed in suitable "running" or revolving cages, display a variable amount of spontaneous activity. This depends upon many conditions: the stage of the estrus cycle, season, temperature, noise, diet, and other factors. Some rats may not run at all; others cover surprising distances in 24 hours, in some cases as many as twenty to thirty kilometers. Most rats when placed in the revolving cages are sluggish at first and then gradually increase their activity until a more or less constant level of daily running is achieved. All these matters have received detailed attention on the part of previous investigators (Slonaker, 1912; Shirley, 1928).

The type of cage used in our experiments (Slonaker, 1908) is a wire mesh cylinder with a circumference of 1.5 meters, which rotates about an axle with very little friction. Each revolution is recorded by a cyclometer on which the total can be read at any time. Within the revolving cage is a smaller stationary box, with food compartment, in which the animal reposes when not running. A battery of twenty such cages were set up in a large room, which for the most part was quiet and had a fairly uniform temperature. The animals were weighed daily, and during the experiments the quantity of food eaten was measured or controlled.

EXPERIMENTS

Experiment 1.—Twenty young female rats, weighing from 80 to 100 grams, were separated into a group of 10 test animals and 10 litter mate controls. Each rat was placed in one of the running cages and was allowed to eat as much of the stock diet* of the laboratory as it desired. The animals and the food were weighed each day and the number of revolutions run was recorded.

*Casein 16, cornstarch 44, yeast 10, salt mixture 4, cod liver oil 10, alfalfa 2 and lard 14.

After a control period of three weeks, when the level of activity seemed stabilized, the ten test rats were changed to a diet deficient in Vitamin B complex. This consisted of washed "vitamin-free" casein 17, cornstarch 64, cod liver oil 10, Crisco 5, and salt mixture 4. On this diet, even though unrestricted in amount, rats soon begin to lose weight; whether because of lack of appetite or because of some specific effect of vitamin deficiency is not certain. The ten control animals continued to receive the stock diet, but the quantity was limited so that they lost weight at about the same rate as the rats on the deficient diet. Thus they served to control any nonspecific effects of inanition. Aside from loss of weight all of the animals appeared well throughout the experiment.

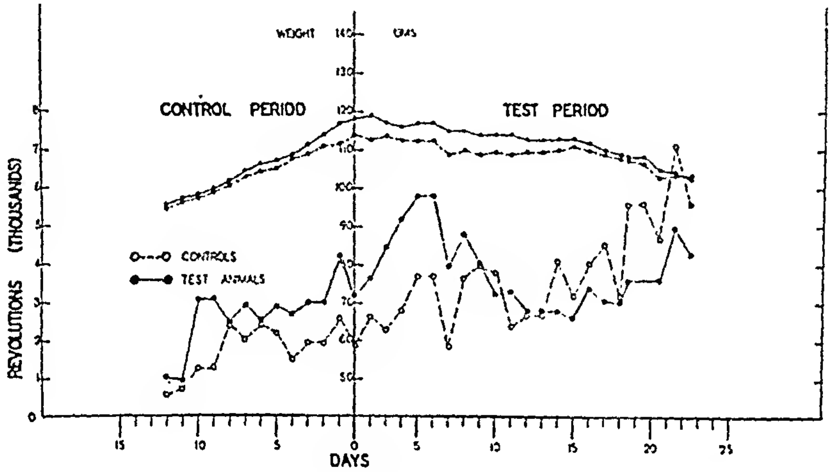

Fig. 1.—Summary of Experiment 1. The first portion of the control period is not shown.

Results of Experiment 1.—The first point to be noted is the great individual variations in activity. These seem important and will be discussed below, but we will present first a composite picture of the test and control animals. Fig. 1 gives the results. The average number of revolutions run daily by the rats in the two groups is shown along with the average weights. The test animals, during the last ten days of the control period, had reached an approximate level of activity in the vicinity of 3000 revolutions. From the start of the test period there is an increase in activity of both sets of rats. This increase, however, is much more marked with the animals on the deficient diet, and within a few days activity is double the control level. The difference in the two groups is statistically significant. After reaching a peak at the fifth day, activity of the test animals falls off rapidly, and within 10 days is back to the control level. A few days later there is again an increase in activity, which coincides with rapid weight loss to a point where the animals' lives are in danger.

In contrast to the test animals, the controls show an entirely different pattern. There is to be sure a slight initial gain in activity, but there is never any drop; from the 15th day on, coincident with rapid weight loss from food restriction, there is a great increase in activity which surpasses that shown by the test animals.

The weight curves require a separate word. During the control period there is the usual brisk gain, almost in a straight line, which occurs with rats of this age on the stock diet of the laboratory. Change to the Vitamin B deficient diet is followed by an immediate slackening in the rate of gain and within a day or two by weight loss, gradual at first, but after approximately two weeks more rapid. The sharp spurt of activity and the subsequent fall are not related to any change in type of the curve of weight loss.

Discussion.—Statistical analysis of the curves of Experiment 1 indicates that the following conclusions may be reliably drawn: (1) Vitamin B deprivation and/or limitation of food intake increase activity initially; (2) limitation of the amount of the normal ration causes progressive rise in activity; (3) vitamin B deficiency after the initial phase of stimulation results in a progressive depression relative to the activity seen in the controls, so that the final (premortal?) stimulation is much less than is to be expected from comparison with the controls in the same state of inanition.

The cause of the increased activity of the rats on the Vitamin B deficient diet is not clear. Guerrant and Dutcher (1940) suggest nervousness from vitamin deprivation as one explanation. However, their young rats which had not reached a steady level of activity before the experiment was started showed increased activity for a period of weeks, an entirely different situation from our experiment in which older rats at a level of activity show only a brief spurt after vitamin deprivation. In other words, a fall in activity in our animals long before serious signs of deficiency are present cannot be well explained on this theory. Another possibility is that change to an inadequate diet which may be distasteful stimulates increased activity in the search for more palatable food.

One can hardly draw any practical applications for man from these experiments, but they suggest that a brief deprivation of Vitamin B may not lessen spontaneous activity, but rather the contrary. It also appears that in rats, at least, restriction of the total amount of food, as in our controls, provided additional vitamins are not fed, tends to increase spontaneous activity slowly over a period of at least three weeks. The final answer to the cause of this phenomenon is not at hand. It is suggestive, however, that in the controls of Experiment 2, to be presented below, where an adequate Vitamin B intake was assured by feeding it to each rat, the same limitation of food did not result in a progressive rise in activity. Hence it is possible that the slow increase in running in the control group in Experiment 1 was the expression of a slowly developing B deficiency brought about by the limitation of food intake and with it of available Vitamin B.

The Results in Individual Rats.—As indicated above, there were striking variations in the activity of individual rats both in the test and in the control series. Among the test animals, for example, No. 6 did not run at all during the entire experiment (see Fig. 2*A*). The cyclometer stood at zero not only during the control period on stock diet but after the Vitamin B deficient diet was instituted. There was no "premortal" increase of activity in spite of very rapid weight loss. The theories discussed above in connection with the composite curve (Fig. 1) all break down as explanations of this animal's

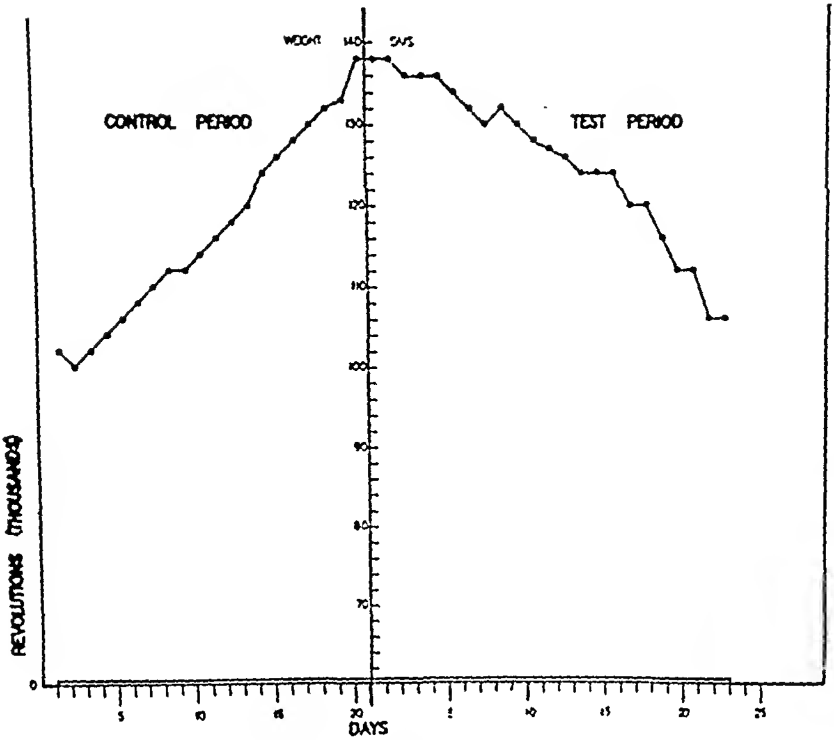

Fig. 2A.

Fig. 2 (*A*, *B*, *C*, *D*, *E*).—Weight curves and activity of individual rats of Experiment 1. See text.

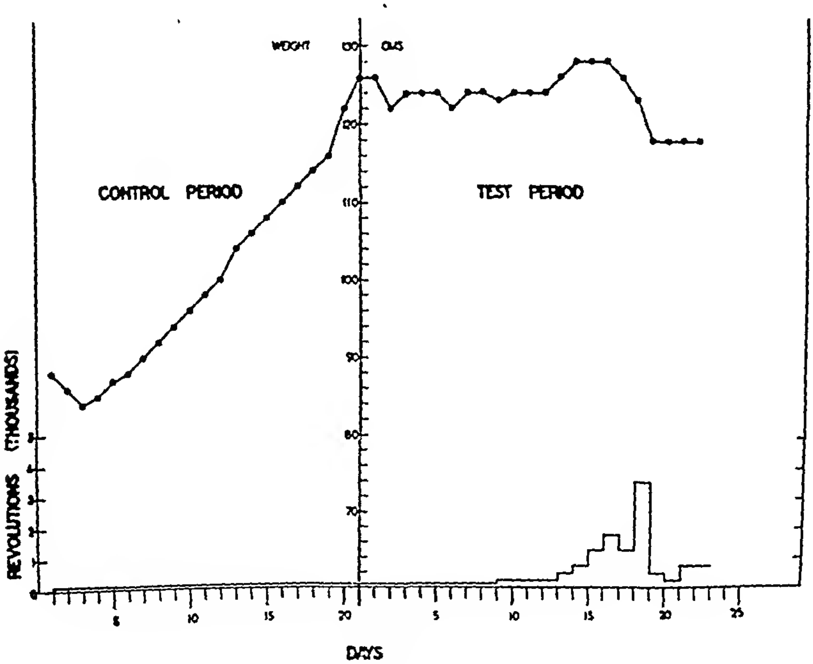

Fig. 2B.

behavior. Rats 5, 4, 2, and 8 of the test series failed to run during the control period and during the early days of the deficiency period, but finally showed slight activity beginning respectively on the seventh, ninth, thirteenth and fifteenth days. There was no correlation, however, between the degree of such activity and the fall in the weight curve (see Figs. 2*B* and 2*C*). Five animals of the test series (Nos. 1, 3, 7, 9, and 10) began to run after the start of the experiment, and by the end of the control period were very active, although the pattern varied in different rats. In No. 7 for example (see Fig. 2*D*) activity was still rapidly increasing at the end of the control period. This rise continued sharply for 6 days; there was then a slight fall with a secondary marked rise even though the animal was not losing weight rapidly at that time. No. 3 (see Fig. 2*E*) failed to show any definite terminal rise in activity even though it was losing weight rapidly.

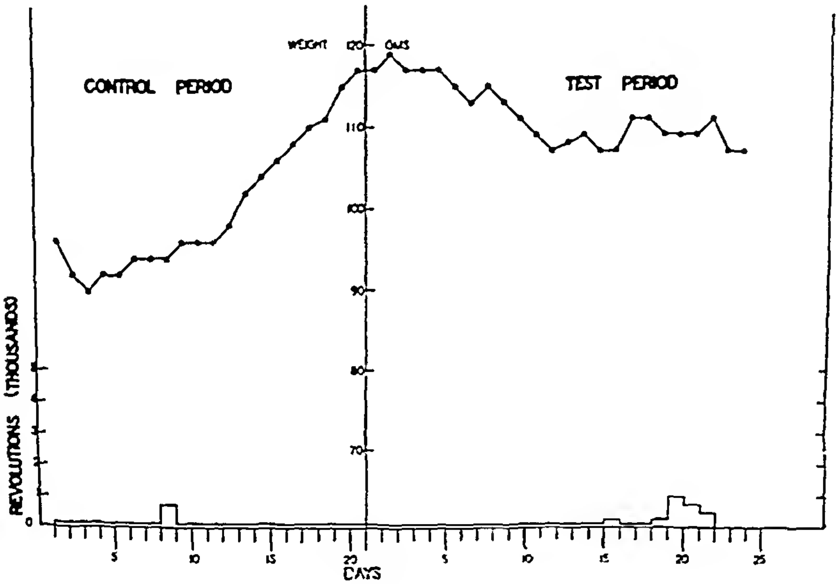

Fig. 2*C*.

Among the control series there were also various types of reaction. One animal failed to run throughout the whole experiment. But whether or not the animals ran during the control period, activity during the test period always increased, even if only slightly, and never showed the invariable spurt of increased activity followed by decline exhibited by the test animals.

Experiment 2.—Because of the possibility that in Experiment 1 the factor responsible for the changes was the alteration in food, rather than the lack of Vitamin B, a second experiment was run in which the food remained unchanged throughout for both groups of rats, and Vitamin B was administered separately. During the control period both test and control animals were placed on the Vitamin B deficient ration described above, but in addition each received 1 c.c. daily of a Vitamin B concentrate which contained according to the manufacturer's statement, in 30 c.c., Vitamin B_1 1500 International Units, riboflavin 1.2 mg., vitamin B_6 4.5 mg., pantothenic acid 12.0 mg., nicotinic acid 60.0 mg. It was also said to contain the filtrate factor (Jukes-Lepkowsky

value of 28 per c.c.).* This vitamin concentrate was fed separately to each rat, mixed with a few drops of water. At the end of the second control period of 21 days the Vitamin B supplement was withdrawn from the test rats. As these rats lost weight, the quantity of food allowed to the controls was restricted so that they too lost at approximately the same rate, but they continued to receive the full dose of B concentrate. During the control period of 21 days the average gain in weight of the rats in Experiment 2 was 18 Gm. This is definitely less than the gain made by the rats in Experiment 1, which averaged 23 Gm. during the comparable period. We interpret this to mean that the B deficient diet plus B concentrate was not as adequate a ration as the stock diet used in Experiment 1.

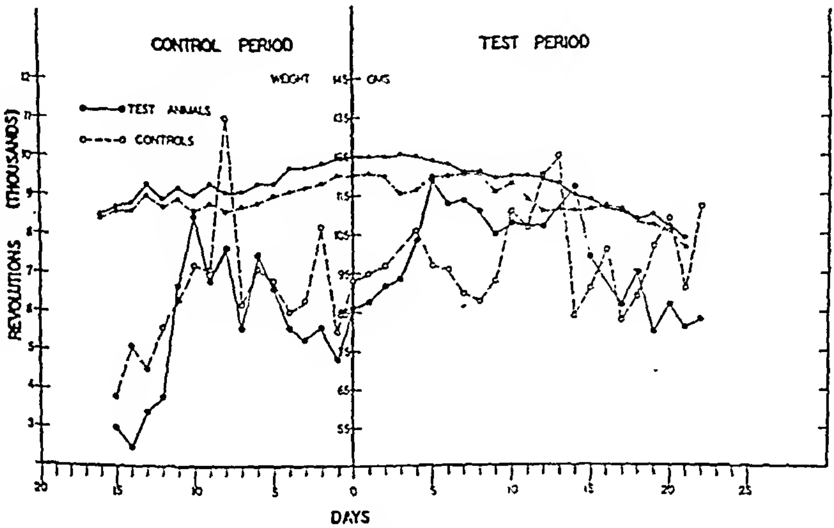

Fig. 3.—Summary of Experiment 2. The first portion of the control period is not shown.

The results (see Fig. 3) are, however, in essential agreement with the first experiment. The animals deprived of the vitamin supplement promptly increased their activity to approximately double the control level; in this case the high level was maintained for a longer period than in Experiment 1. However, there was subsequently a fall to the control level. At this point the experiment was modified by restoring the B concentrate to the test group; the results of this procedure will be discussed later. The control group of rats, although showing considerable irregularity from day to day, did not undergo any consistent deviation from their control level. A statistical analysis of the curves demonstrated that the following conclusions were justified:

1. Vitamin B deprivation was followed by a slightly greater increase of activity than deprivation of food alone. The mathematical chances are 18 to 1 in favor of this being a true difference.

2. After the initial phase of stimulation, Vitamin B deprivation produces a progressive depression of activity as compared to the controls whose food intake is limited without vitamin restriction.

*This was a specially fortified product supplied for this study by the Galen Co., Inc., Berkeley, Calif.

After three weeks both sets of animals were restored to the original diet, that is, they all received the B-free diet as desired plus the 1 c.c. of Vitamin B concentrate just as during the control period. The effect on activity is illustrated in Fig. 4. The six days preceding restoration to the original diet are shown, and it is seen that the activity of the test rats was practically stationary, whereas that of the controls was increasing. On the change to the original diet both sets show an immediate drop in activity to a very low level, which during the ensuing days increases gradually and slightly. The meaning of this interesting finding is not clear. Sudden restoration of vitamins which had been lacking does not suffice as an explanation, because the control group, although restricted in quantity of food, had been receiving the full amount of Vitamin B throughout the experiment. It appears that the correction of either lack of Vitamin B or lack of total calories leads to a decrease of activity, which may be due to release of nervous tension or cessation of need for seeking food. It may simply be that the rats, whose food intake approximately doubled during the first few days of unrestricted diet, were busy eating and therefore ran less, or that the unusual distention of their gastrointestinal tracts caused a disinclination to exercise.

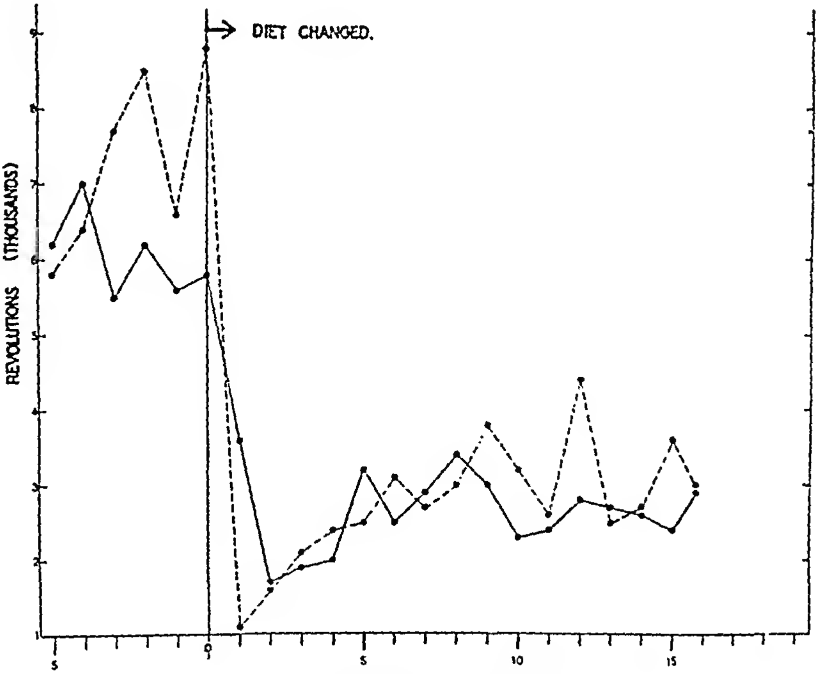

Fig. 4.—Effect on activity of restoration of diet to the conditions obtaining during the control period of Experiment 2.

DISCUSSION AND SUMMARY

To summarize briefly, the object of these experiments was to discover the effect of Vitamin B deficiency on spontaneous activity of the rat. Two experiments along somewhat different lines were done so as to be sure of adequate controls. It was found, in agreement with previous observers, that rats placed in revolving cages do not run at first; they seem to have to learn. In our

observations there was an increase of activity during approximately the first two weeks of the control period; thereafter activity remained more or less on a level. There were great variations, however, in individual animals; some did not run at all during the entire experiment; others became active promptly; some were still increasing their activity at the end of the three weeks' control period.

In any event withdrawal of Vitamin B from the diet was followed by a prompt spurt of activity lasting from five to ten days and then followed by a decline to approximately the control level. This phenomenon occurred with great regularity and was strikingly different from the behavior of the control animals whose food intake was curtailed. These rats showed a slower but continued increase of activity, which went on, with no drop, throughout the course of the experiment, unless a special supplement of Vitamin B was administered.

The explanation of the sharp spurt of activity shortly after vitamin deprivation is not clear. The suggestion of Guerrant and Dutcher that B deficiency causes "nervousness" does not seem adequate to us: first, because the effect is so very prompt, and, second, because there is no evidence that nervousness in the usual sense of the word gives rise to increased running in this type of experiment. During the period of Vitamin B deprivation our rats were very restless, excitable, and difficult to handle. However, this variety of "nervousness" does not necessarily result in increased running, as has been amply demonstrated by one of us (T.) in studies to be reported later. The running response probably requires a conscious purposeful coordinated "drive," which is quite different from the lack of neuromuscular poise or restlessness which is usually called "nervousness." The simplest view would seem to be that shortage of either vitamin or food stimulated the animals into a reaction pattern which would be helpful in the search for a more desirable diet. The drop in activity of the vitamin deficient rats following the initial stimulation seems on the other hand specifically related to Vitamin B lack since it does not occur in the controls. It should be noted that this slowing of activity occurred in our animals long before they showed any visible evidence of deficiency disease; it cannot be regarded at all as an agonal phenomenon.

The sudden drop of activity of rats when either Vitamin B or unlimited calories is restored after a previous period of limitation is also of great interest (see Fig. 4). The only satisfactory explanation is that the fulfillment of a dietary need of any sort is followed by greater food intake, more time spent in feeding, and subsequently in sleeping, and the cessation of the urge to run associated with unsatisfied cravings. This is probably similar to the satiation and tendency to inactivity commonly experienced after an unusually large meal.

Finally, one is tempted to speculate on the bearing of these findings on problems of human nutrition. The suggestion comes forth that in situations where only a small bulk of food can be available, such as in the case of parachute troops or in castaway rations, the supplying of Vitamin B might be just as important over periods of a few days as adequate calories. Our experiments also suggest that Vitamin B deficient diets can cause alterations in

behavior which may precede by many days any other clinical evidence of the vitamin deficiency and may in fact be the only symptom of such deficiency in the subclinical stages.

CONCLUSIONS

1. Limitation of Vitamin B in the diet of the white rat is promptly followed by increase in activity.

2. After a period of a few days to two weeks there is a sharp decrease in activity.

3. This decrease is not to be explained by inanition, since control fasted rats whose Vitamin B intake is maintained at a constant level continue to show normal activity.

4. When rats whose diet has been deficient in either Vitamin B or in total calories are furnished unlimited food and adequate vitamins, there follows, not an increase, but a sudden sharp fall in activity, which persists during the period of increased food intake.

5. Some possible explanations of these phenomena are discussed.

THE REACTION OF LEUCEMIC PATIENTS TO THE SULFONAMIDES

E. L. Amidon, M.D.,* Burlington, Vt.

OUR knowledge of the effectiveness of the sulfonamides on certain infectious diseases is rapidly becoming definite and accurate. Our knowledge of the pharmacologic action of the several forms is still accumulating. The earliest report[1] indicated that the drugs produced a bacteriostasis. The suggestion of the neutralization of the bacterial toxins[2] could only be a partial explanation. Very early it was learned that the temperature greatly affected the activity of the drug. The fact was still left unexplained why certain bacteria were either prevented from multiplying or were killed outright, while other bacteria were seemingly unaffected. Observations of later date suggest the importance played by the medium.[3, 4] It would seem rather certain at the present time that the sulfonamides may destroy certain substances necessary for bacterial multiplication,[5-7] and it is with this theory we are chiefly concerned.

Much experimental evidence has accumulated concerning the toxic effects of the drug. For our purposes only that effect on the white blood cells will be considered. Young[8] apparently was one of the first to report complete agranulocytosis. Many others have demonstrated this change and have offered several explanations. The conclusion of Bliss and Long,[1] that with the exception of toxic changes associated with malignant neutropenia there was no direct effect upon the white cells of the patient, seems adequate. It should be noted that the severe cases of neutropenia usually occur only after the drug has been administered for some time, generally from two to four weeks. Goodman and Gilman[9] suggest that this reaction is dependent upon the factor of personal idiosyncrasy, adding that the reaction is rare. Attention should be called to the fact that when an infection is accompanied by a leucopenia, the administration of the drug may result in a rapid rise in the number of granular white cells.

It remained for Livingston and Moore[10] to demonstrate the effect of sulfapyridine on the white blood cells of patients with leucemia. They administered sulfapyridine to six cases of lymphatic leucemia and reported a definite and marked change in the total number of lymphocytes in the peripheral blood. The first patient with chronic lymphatic leucemia was treated on four separate occasions. The drop in white cells was: from 256,000 to 6,500; from 33,000 to 11,000; from 47,000 to less than 20,000; and from 94,000 to slightly over 20,000. Although this patient was treated late in 1939, the outcome was not stated. Their second patient who apparently developed signs and symptoms of acute lymphatic leucemia showed a drop in the total white count from 212,000 in successive stages of: 183,000 to 100,000 to 60,000 to 40,000 and finally to 20,000. There was no stated evidence of any clinical improvement, and they state that

*Associate Professor and Chairman of Department of Medicine, The College of Medicine of the University of Vermont.
Received for publication, April 9, 1943.

the drug was discontinued on the 19th day because "in spite of the change in blood picture there was clinical evidence of widespread leucemic infiltration."

Following the lead suggested by Livingston and Moore four cases of lymphatic leucemia were studied, and the results tend to agree with those found by the previous investigators.

CASE 1.—Mrs. O. B., 36-year-old, white, was admitted May 4, 1941, complaining of general weakness, edema of the legs, and sore throat of one-week duration. Several small lymph nodes were found in the neck and groin. The spleen was only slightly enlarged. Her blood count showed: hemoglobin, 55 per cent; red cells, 2,520,000; and white count as given below. Several small macular areas and small ecchymotic areas were noted on her legs. In Table I are listed her blood counts with her therapy and progress:

5/ 8	5,400	43	Neutrophiles, 57 per cent.
5/11	7,200	56	Neutrophiles, 44 per cent. Discharged from hospital.

The patient left the hospital with a blood picture of: hemoglobin, 58 per cent; red cells, 2,860,000; and a white count as given above. She received no more of the sulfonamides.

Twenty-seven days after her discharge she was admitted to another hospital. On admission her white count was 32,000 with 97 per cent lymphocytes. On June 14, ten days after admission, with her white count 16,900, she was given sulfathiazole in 1 Gm. doses every four hours. The following day her white count dropped to 3,600, and four days later it was 400, dropping to 300 on the following day. Eight days after sulfathiazole was begun the patient died. Post-mortem examination revealed atrophic bone marrow and splenomegaly. The anatomic diagnosis was acute lymphatic leucemia.

CASE 2.—J. D., a 76-year-old white male, was admitted Sept. 24, 1941, complaining of fatigue, dyspnea, palpitation, and precordial discomfort. His blood count on admission was: hemoglobin, 26 per cent; red cells, 904,000; white count, 306,000; 96 per cent lymphocytes. In Table II are listed his blood counts with his therapy and progress.

TABLE II

DATE	WHITE CELLS	LYMPHOCYTES	REMARKS
9/24	306,000	99	
9/25	576,000	100	Sulfathiazole started 1½ Gm. every four hours for two doses. Pulse weak and thready, respirations rapid and labored, transfused with 750 c.c. blood.
9/26	450,000	99	
9/27			Sulfathiazole started ½ Gm. t.i.d.
9/30	297,600	98	
10/ 2	409,000	99	Patient died.

This patient showed symptoms of vascular collapse only one hour after the second dose of sulfathiazole was given and received only ½ Gm. three times a day after the 27th.

Case 3.—E. P. (H. H.), a 30-year-old white female, for the preceding two weeks had suffered from canker sores in mouth, dysuria, and frequency. A blood count taken during this time showed a hemoglobin of 50 per cent; red cells, 2,400,000; white cells, 6,000 with 24 per cent polys and 76 per cent lymphocytes. She developed abdominal distention and progressive weakness and was admitted to the hospital. Her physical examination on admission showed no enlargement of the spleen or liver, and no enlarged lymph nodes were found. In Table III are listed her blood counts with therapy and progress:

TABLE III

DATE	WHITE CELLS	LYMPHOCYTES	REMARKS
9/29	34,000	90	
10/ 1	46,350	82	Transfused 400 c.c. whole blood.
10/ 3	47,400	90	Sulfathiazole 1 Gm. t.i.d.
10/ 5	37,000	90	
10/ 6	31,000	94	
10/ 7	29,700	93	Patient felt fine, temperature normal for past 24 hours. Sulfathiazole stopped, total of 9 Gm.
10/ 8	23,800	92	
10/10	20,150	86	
10/11	17,550	88	
10/12	18,350	87	
10/14	14,300	72	During past five days has improved, temp. normal.
10/16	42,250	70	Sudden rise in temperature—104° F.
10/17	48,050		Sulfathiazole started, 1 Gm. t.i.d.
10/18			Temperature lower, condition same.
10/20			Patient died.

The patient developed a terminal pneumonia. A post mortem was performed; the diagnosis was acute leucemia.

CASE 4.—H. D. W., a 68-year-old white male, was admitted March 8, 1942, in extremis. About two months previous to admission the patient first noticed a mass in the left axilla which had increased in size. Two weeks previous to admission he noticed several masses in the left side of the neck. These masses also had progressively increased in size. Physical examination revealed enlargement of the liver and spleen. Discrete, nontender, and moderately firm lymph nodes were found in both sides of the neck, axillae, groin, and popliteal spaces. In Table IV are listed his blood counts with his treatment and progress. The temperature which was at 103° dropped progressively after sulfanilamide was given to 100°. The report of the biopsy was acute leucemia, type not determined. On the 18th the patient was well enough to be up and about. His appetite improved as well as his general condition and he was allowed to go home.

The patient was readmitted on May 29, 1942, with a semifluctuant mass on the anterior surface of his right leg, of ten days' duration. He had been well enough to return to his former job as janitor, until ten days previously when he developed "flu." He was referred to the hospital for treatment of the leg. Physical examination revealed large lymph nodes

throughout body as well as enlarged liver and spleen. The mass on the leg became definitely fluctuant and was incised and drained five days after admission. In Table V are listed his blood counts with his treatment and progress.

The patient ran a septic temperature ranging from 100.4° to 102° for the first four days, after which it ranged between 97° and 101.° The glands in the neck decreased in size during his stay in the hospital.

After the patient's discharge from the hospital, the lymph nodes again enlarged and he grew progressively worse, dying in July of the same year. He did not receive any of the sulfonamides after leaving the hospital.

DISCUSSION

The first patient, suffering from acute lymphatic leucemia, reacted promptly to the administration of sulfanilamide and sulfathiazole by a drop in the total

white cells, followed by clinical improvement from a moribund state to that of comparative health. Contrary to prevailing teachings, the lymphocytes were decreased while the number of neutrophiles remained nearly constant. Because of the prolonged leucopenia, it was thought best to discontinue the sulfonamides.

Patient 2 showed the smallest hematologic change after the administration of sulfathiazole. He received only six Gm. over a four-day period. The sudden vascular collapse after the administration of sulfathiazole is difficult to explain.

The third patient like the first had the acute form of the disease and rallied from a nearly moribund state after sulfathiazole was given. The clinical improvement was marked. It is quite apparent that the drug should have been continued.

The fourth patient, suffering from acute lymphatic leucemia, was in extremis on admission. He responded so well to sulfanilamide that he was able to be discharged from the hospital and was able to return to his job as janitor. On this admission he responded well to sulfathiazole but failed to show any change when sulfadiazine was given.

CONCLUSIONS

It appears that certain of the sulfonamides may produce a rather sudden drop in the circulating lymphocytes in lymphatic leucemia. This does not occur in myelogenousleucemia.[10] That this reaction is not of a toxic nature is best indicated by the suddenness of the reponse and by the fact that there is usually an improvement in the patient's condition.

The suggestion of Stamp[4] and Woods[6] that sulfanilamide may interfere with some "growth factor" inhibiting the development of bacteria is worthy of consideration. Is it possible that the drug acting in a similar manner inhibits the multiplication of lymphocytes? If this is so, it is peculiar that similar results do not occur in myelogenous leucemia, and that sulfadiazine failed to produce similar results.

SUMMARY

Four cases of leucemia are presented, all of which showed a drop in the total circulating lymphocytes, and in all but one, clinical improvement, after the administration of sulfanilamide and sulfathiazole.

I wish to acknowledge with thanks the kindness of Dr. R. E. Miller for the follow-up on Case I, and Dr. W. D. Lindsay in allowing Case 3 to be presented.

THE EFFECTS OF VARIOUS INTENSITIES OF LIGHT ON CERTAIN LABORATORY ANIMALS*

MARK E. MAUN, M.D., AND LUVERNE H. DOMEIER, M.D.
DETROIT, MICH.

I. INTRODUCTION

IT IS a common belief that sunlight and well-lighted rooms are healthful. Physicians and lay people assume that sunlight and artificial light are not only beneficial in the treatment and prevention of many diseases but that they promote growth as well. But sunny days and well-illuminated rooms create a desirable environment for most individuals so that the effect of increased light on their well-being is difficult to measure. An obvious lack of control of one's environment makes it yet more difficult to measure the effect of light on the physical, as differentiated from the mental, health of a given group of individuals.

Numerous studies have been made to show the value of ultraviolet therapy, but only a few studies have been made of the effect of visible light on the health and the growth of man and of experimental animals.[6, 24] In our experiment we have attempted to study the influence of various quantities of visible light on the health, the growth, and the behavior of certain laboratory animals.

II. EXPERIMENTAL ROOMS

A. Room Construction.—Three animal rooms were constructed so that no extrinsic light entered them. The rooms measured approximately 16 feet in length, 10 feet in width, and 9 feet in height. Animal cages were placed along one wall of each room, and over them lighting equipment consisting of banks of fluorescent tubes attached to aluminum-covered reflectors was suspended approximately 36 inches above the floors of the cages. The fluorescent tubes were intended to produce approximately 3 foot-candles in one room, 100 foot-candles in the second room, and 1000 foot-candles in the third room. The amount of illumination was measured on the floors of the animal cages. The rooms will be referred to as the 3, the 100, and the 1000 foot-candle rooms, although the levels of illumination did not always reach or remain at the 3, the 100, and the 1000 foot-candle levels (See Chart I).

*From the Department of Pathology, Wayne University College of Medicine, Detroit, Michigan.

Aided by a grant from the Detroit Edison Company.
Received for publication, April 21, 1943.

B. Lighting.—White fluorescent lamps were used in all three rooms to produce the required illumination. The spectral quality of the light is shown in Chart II. Three 15-watt lamps were sufficient to produce 3 foot-candles, while twelve 30-watt lamps produced more than 90 foot-candles in the second room. Sixty-four of the 40-watt lamps plus sixteen of the 30-watt lamps were needed to produce more than 900 foot-candles in the so-called 1000 foot-candle room. The intensity of illumination was measured periodically with a MacBeth illuminometer. Weekly cleaning of the fluorescent tubes to remove dust films was found to prevent a reduction of light output. Some loss of light intensity was noted, however, as the tubes aged, and tube replacements were necessary.

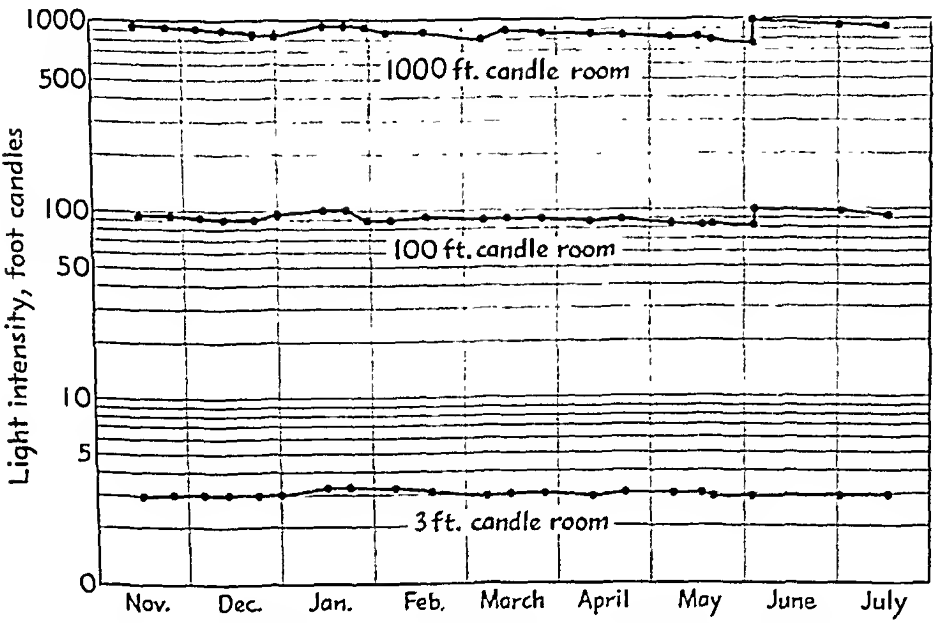

Chart I.—Intensity of light on the floor of the animal cages.

C. Animal Cages.—Animal cages were constructed of thin wire (0.4 mm.) mesh (1 cm. sq.) which permitted a maximum exposure to light; in spite of this precaution, however, there was a loss of approximately 20 per cent as the light passed through the wire mesh. Measurements of light were made inside the animal cages. Glass shields were placed as covers for the cages in the 1000 foot-candle room after removal of the wire tops in an attempt to equalize the radiant energy in the 100: and the 1000 foot-candle rooms. The glass shields were used to absorb and dissipate by convection a considerable portion of the long-wave radiant energy given off by the lamps. The glass covers reduced the radiant energy intensity from 172 British thermal units per square foot per hour to 157 British thermal units per square foot per hour, which figure was considered comparable to 144 British thermal units per square foot per hour found in the 3 and the 100 foot-candle rooms.

D. Temperature and Humidity.—Ventilation of the three rooms was maintained by a 3500 cubic-foot-a-minute fan pulling the warm air of the building into the rooms through light-proof ventilators and exhausting it through a fourth outer room. The air inlets and exhausts were arranged to minimize drafts

on the animals and at the same time to maintain a constant change of air in the rooms. The air velocity in the cages was approximately 15 feet per minute. No attempt was made to control the air temperature or the humidity of the rooms except to avoid extremes. The temperature and the humidity are recorded in Chart III, the peaks seen in the humidity record being due to the washing of the floors and of the fluorescent tubes.

In addition to continuous recordings of the temperature, frequent temperature readings were taken from thermometers placed in the animal cages. In the early days of the experiment the temperature in the 1000 foot-candle room ranged from two to three degrees centigrade higher than in the other rooms, but this elevation subsequently varied less than 1° C. with improved ventilation. These temperature differences were noted after five to six hours of lighting.

E. Time of Exposure.—The animals were exposed to the light in groups varying in size according to the available animal space. The lights were turned on by a time clock at 6 A.M. and turned off at 6 P.M. This period was followed by total darkness. An effort was made to expose the animals from the youngest age at which they could be isolated to young adult life. Although most of the animals were placed in the experimental rooms at 4 to 8 weeks of age, cockerels were placed in the rooms at 48 hours of age. The period of exposure of each animal varied with its health; infection often reduced the duration of the period, for animals were sacrificed if it appeared that infection would be fatal. Healthy animals were sacrificed at the termination of an arbitrarily chosen growth period.

F. Animal Care.—All animals were given superior care and attention. The cages were kept scrupulously clean, and sick animals were promptly placed in isolation cages, where they continued to receive, nevertheless, the same exposure to light. A large Toledo scale was provided for weighing the animals at four-to-five-day intervals.

III. ANIMALS

Guinea pigs, rabbits, rats, and leghorn cockerels were used in the study. These animals were used because of our familiarity with them and because of the ease with which they can be handled. Since some of this group might be considered nocturnal, there is some doubt as to the wisdom of the selection. Many of the guinea pigs and rabbits were albinos, but there were some mixtures of color. The rats were all albinos, and the chickens were all white leghorns.

Animals of both sexes were used, and an attempt was made to obtain litter mates. There was difficulty, however, in obtaining them, and even when they were obtained, the destruction of a litter by loss of one or more animals made the consideration of litter mates of doubtful value in the final analysis. The cockerels were chosen indiscriminately.

The animals received unlimited quantities of food from shielded hoppers which were so constructed as to allow a minimum amount of food to be exposed to the light. The rats were given ground dog chow, while the rabbits and the guinea pigs received rabbit chow. The chickens were given a varied diet consisting of chicken mash, cracked corn, sour milk, oyster shells, and occasionally some ground dog food. Water in unlimited amount was furnished to all animals by means of continuous feed bottles. The water in the cages of the rabbits,

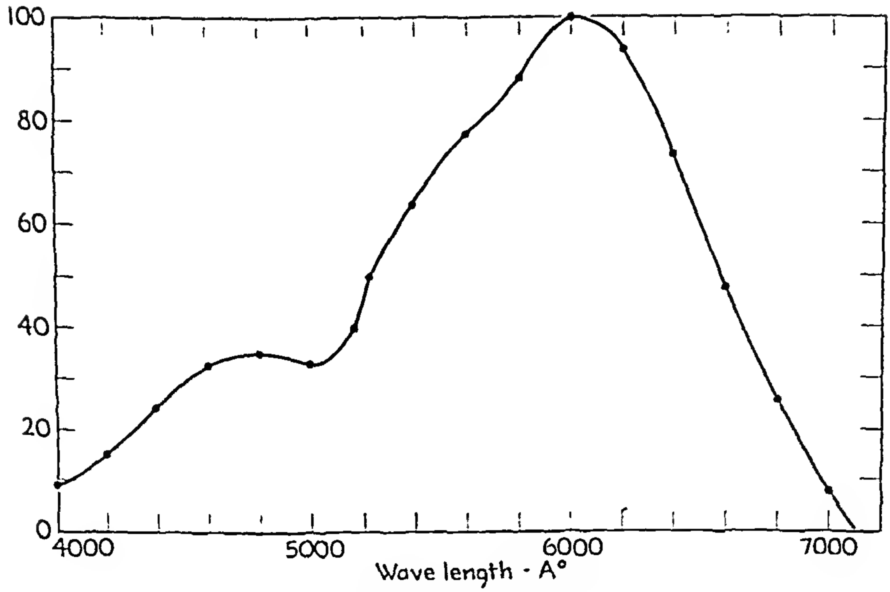

Chart II.—Spectral quality of light in the animal rooms.

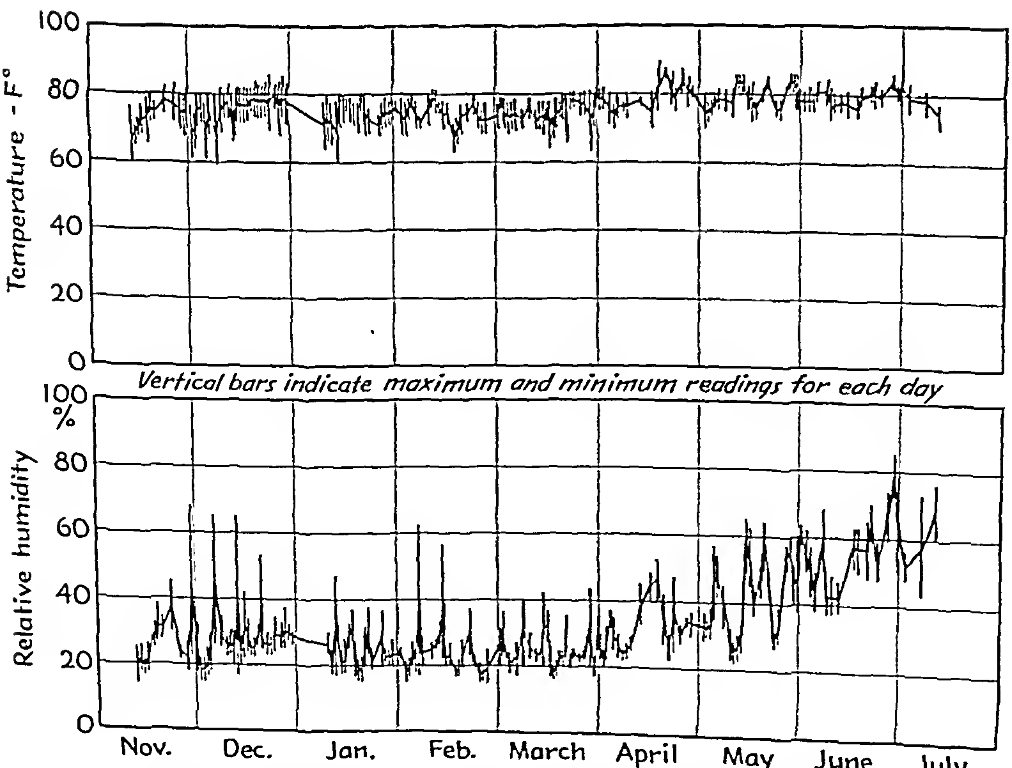

Chart III.—Record of temperature and humidity in the animal rooms.

the guinea pigs, and the chickens was necessarily exposed to light, but the water drunk by the rats was protected in feed bottles. Accurate measurements of the quantity of food and water consumed were not made, but we believe that the amount of food consumed was approximately the same in all rooms. More water was apparently consumed in the 1000 foot-candle room.

IV. RESULTS

A. General Behavior of Animals

1. Activity and Comfort.—The experimental animals were observed closely to determine whether there were any differences in their reactions to exposure to the varying quantities of light. In general there were only slight differences, and these were most evident in comparing the animals in the 1000 foot-candle room with those in the other two rooms. Rats exposed in the 1000 foot-candle room seemed at times to be apathetic, and it was noted that they did not huddle, but tended to lie apart and upon their backs. The rats were most apathetic when the temperature in the 1000 foot-candle room exceeded that of the other rooms, so we attributed some of the differences in activity to the differences in temperature. Rabbits and guinea pigs seemed to be equally active in all rooms. The cockerels in the 1000 foot-candle room had a tendency to pant more readily than the birds in the 3 and the 100 foot-candle rooms. All experimental animals in the 100 foot-candle room were as comfortable and active as animals in the 3 foot-candle room. Apparently the intensity of light does not prove uncomfortable to animals if the temperature is not elevated.

2. Health.—The health of the animals was as good as could be expected in view of the fact that animal quarters were limited. In all rooms some of the rabbits developed numerous attacks of severe diarrhea associated with anorexia and marked loss of weight. These infections proved to be highly contagious so that prompt isolation was necessary. Though a few of the animals succumbed to infection, the majority of them recovered without specific therapy. The considerable weight loss by the rabbits during infection was promptly regained with improved health.

The rats remained in excellent health throughout the experiment, and losses were negligible. Respiratory infections and snuffles were at a minimum while the growth and the gain in weight were constant.

The guinea pigs remained in good health in all experimental rooms during the first ten to fifteen days of the experiment, but after this period they developed shaggy hair, anorexia, diarrhea, muscle weakness, and marked loss of weight, and were sacrificed. We believe that the picture was similar to experimentally produced vitamin C deficiency.

The cockerels were in excellent health throughout the entire experiment. A few of the unfeathered birds succumbed in the early days of the experiment because of low temperature for chicks. Subsequently the chickens were vigorous and very active. Those in the 1000 foot-candle room panted with an elevation of temperature.

3. Sensitivity to Light.—The experiment provided an opportunity for observing the reactions of the animals to high levels of illumination. Our daily observations should be of some practical value, for animals may be more sensitive to light than man. We paid particular attention to behavior, to at-

tempts to hide, and to the appearance of the feathers or of the animals' skin. As far as we could determine, all animals appeared to be unaffected by the high levels of illumination in the 100 and the 1000 foot-candle rooms. No attempts to hide from the light were noted. Examination of the skin of the animals revealed the color, the texture, and the vessels to be comparable in all rooms, and no evidence of abnormal pigmentation was present. The feathers of the chickens were normal to gross examination; the combs of the chickens in all rooms appeared to be paler and larger than normal. This latter change was attributed to the minimal amount of ultraviolet rays present in the light.

Chart IV.—Record of the growth of female rabbits.

4. Growth.—Charts IV through X furnish evidence of the growth of the experimental animals. The rate of growth per day was considered a fair index of the effect of the varying quantities of light upon the animals, and comparison of the growth of all animals in the 3, the 100, and the 1000 foot-candle rooms has been made. Only the animals that survived the experimental period and those living sufficiently long to be significant are compared in the charts.

a. Rabbits.—Examination of Chart IV reveals the growth record of 25 female rabbits, an obviously small number. The growth period of the animals was variable because of the loss of some of the animals by infection. The

average daily weight gain was practically the same; the average gain of the animals in the 1000 foot-candle room, 27.04 grams, was only slightly greater than that of the animals in the 100 and the 3 foot-candle rooms, 25.62 and 22.63 grams respectively. The comparison of litter mates, as suggested before, did not prove to be useful. Only a few male rabbits survived the experimental period so that any study of their relative growth would be of little value. In the course of the experiment it became evident that the maintenance of health in rabbits in small quarters is difficult.

Chart V.—Record of the growth of guinea pigs.

b. Guinea Pigs.—The 36 guinea pigs placed in the experimental rooms apparently developed scurvy so that for the purpose of this experiment the group was unsatisfactory. The healthy guinea pigs placed in the experimental rooms were given dog chow and were not allowed lettuce or similar food because of the desire to avoid an exposure of the food to light. As previously stated, the animals remained healthy for a period of ten to fifteen days, after which time they developed shaggy hair, some muscular weakness, and subsequently a marked fragility of the bones. Litter mates in all three rooms became sick at approximately the same time. Since the pigs received no other food than the dog chow, we were of the opinion that they developed vitamin C deficiency. Analysis of Chart V shows that the guinea pigs were in the experimental rooms approxi-

mately two weeks. The brief exposure period and the vitamin C deficiency present make comparison of these animals unsatisfactory. The average daily weight gain during their growth period was 3.08 grams for the male pigs in the 3 foot-candle room and 3.39 and 3.15 grams respectively for the male pigs in the 100 and the 1000 foot-candle rooms. Similar small differences were noted in the female pigs, but the gain was greatest in the 3 foot-candle room and smallest in the 1000 foot-candle room. A comparison of the litter mates showed wide variations in the average weight gain (Chart V).

Chart VI.—Record of the growth of albino rats.

c. *Rats.*—The 56 rats proved to be satisfactory animals in this experiment. These animals remained in good health throughout the experimental period, and most of them were sacrificed after being in the experimental rooms approxi-

mately fifty days. Chart VI gives a comparison of the growth of the 41 male rats. It reveals that the average daily weight gain of the male rats in the 3 foot-candle room (2.61 grams per day) exceeded that of the male rats in the 100 foot-candle room (2.33 grams) and that of the male rats in the 1000 foot-candle room (2.12 grams). A similar trend is noted in the small group of female rats. The average daily weight gain in the 100 and the 1000 foot-candle rooms was less than that in the 3 foot-candle room. A comparison of litter mates likewise reveals a tendency for litter mates in the 3 foot-candle room to gain more per day than litter mates in the 100 and the 1000 foot-candle rooms. The average daily weight gain of each rat is shown graphically in Chart VII. From a study of this chart it is evident that few animals in the 1000 foot-candle room gained as much as the animals in the 100 and the 3 foot-candle rooms. A study of the growth curves in Chart VIII shows the growth of animals was relatively uniform throughout the experimental period. From this chart one would assume that the beneficial or harmful effect of varying quantities of light was not evident in any particular period of the experiment.

d. Chickens.—A few chicks died in the early days of the experiment, probably because of relatively low temperatures for unfeathered birds, and the hens were discarded from the experiment when they were identified. The remaining 56 cockerels were exposed for approximately eighty-three days and then sacrificed. The health of all birds was good throughout the experiment.

A comparison of the growth of the chickens is tabulated in Chart IX. The cockerels in the 3 foot-candle room gained less (7.89 grams) than those in the 100 foot-candle room (8.07 grams) and more than those in the 1000 foot-candle room (7.47 grams). Chart IX indicates that the different levels of illumination in the experimental rooms did not produce significant variation in the rate of growth of cockerels. Chart X reveals the growth curves of the cockerels to be similar.

B. Specific Observations of Animals

1. Eyes.—The eyes of the animals were frequently observed to study the effect of various quantities of light on the conjunctivae, the wink reflex, and the fundi. Examination of the eyes was done carefully because any possible damage due to light could be more readily detected in the eye than elsewhere.

The conjunctivae of the animals in all rooms were normal to gross examination. There was no tendency of any of the animals to blink frequently or to close their eyes in an attempt to avoid the light.

Fundoscopic examinations were done on a number of rabbits, and several were found to have increased pigmentation resembling chorioretinitis. These animals, however, were not examined until after they had been exposed to the light, and the pigment may have been present prior to their exposure to light in the experimental rooms. In two rabbits a clouding developed in the media, making a clear view of the fundi impossible. Slit-lamp examination of one localized the difficulty in the lens; the other animal died of infectious diarrhea before examination. The fundi of two litters of rabbits, six animals, were studied before their exposure to light in the experimental rooms. Although all six rabbits were albinos, a few pigmented hairs were found on the tips of their tails and on their ears, and some of the group were found to have partially

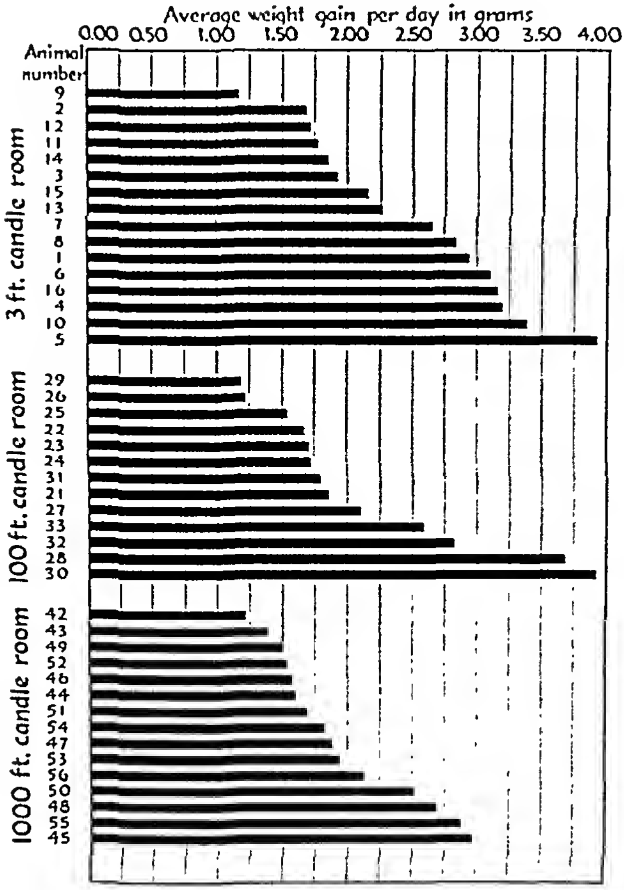

Chart VII.—Average daily gain in weight of rats.

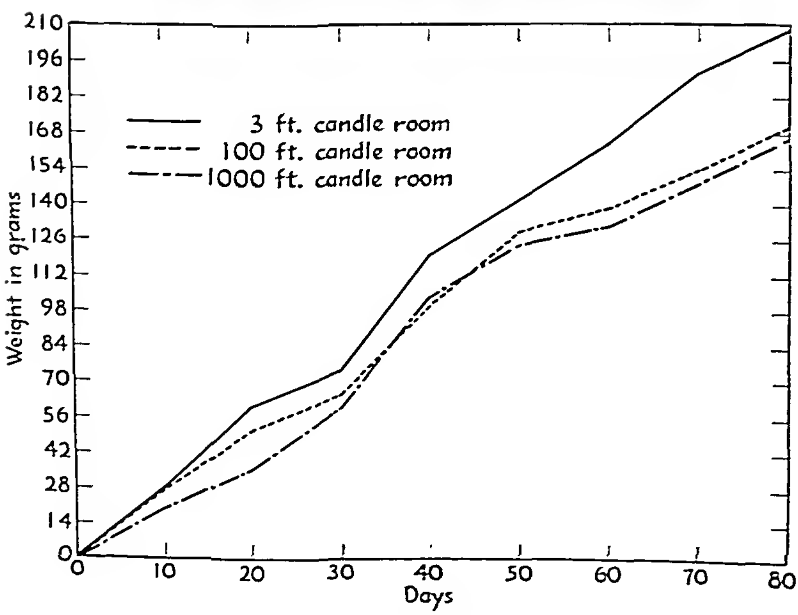

Chart VIII.—The growth curve of rats.

pigmented fundi. The amount of pigment in the fundi did not increase in any of these rabbits after their exposure to light in the 3, the 100, or the 1000 foot-candle room. It was noted that normal black rabbits have a large amount of pigment in their fundi; hence the presence of pigment after exposure to light need not be considered abnormal.

The examining ophthalmologist, Dr. Frances MacCraken, could find no evidence that the eyes of the rabbits were injured by high levels of illumination, but further study on this subject should be done. The eyes were removed for histologic examination.

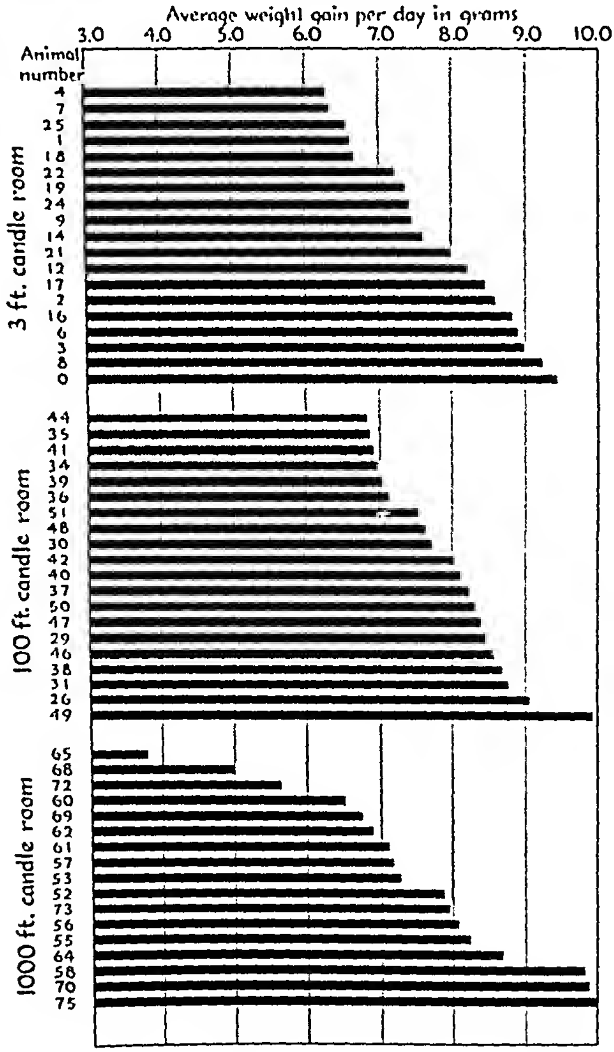

Chart IX.—The average daily gain in weight of cockerels.

2. *Hair and Feathers.*—The hair and the feathers of the experimental animals in the various rooms were compared. No differences could be detected in the texture, the length, the thickness, and the color of the hair or the feathers. The hair of the shorn rabbits and guinea pigs, however, was found to grow most rapidly in the 1000 foot-candle room and least rapidly in the 3 foot-candle

room (Figs. 1, 2). Many rabbits were repeatedly shorn to check this observation. The variation was constant in litter mates. Numerous biopsies of the shorn areas were taken for histologic study.

3. *Laboratory Procedures.*—Only a few laboratory studies were made. Hemoglobin determinations and blood smears were made from a few rats, a few rabbits, and some chickens. Both hemoglobin levels and blood smears were found to be normal and comparable in animals from all the experimental rooms.

C. *Autopsy Studies.*—Autopsies were done on all animals. The majority were sacrificed at the end of the experimental period, but a few died in the course of the experiment.

1. *Gross Studies.*—Rabbits and rats showed no significant gross variations; occasionally a few small areas of bronchopneumonia were noted. Examination of guinea pigs revealed extensive hemorrhages into the muscles of the hind legs and extreme fragility of the bones. The remainder of the organs were essentially normal to gross inspection. The chickens were found to be normal on gross examination.

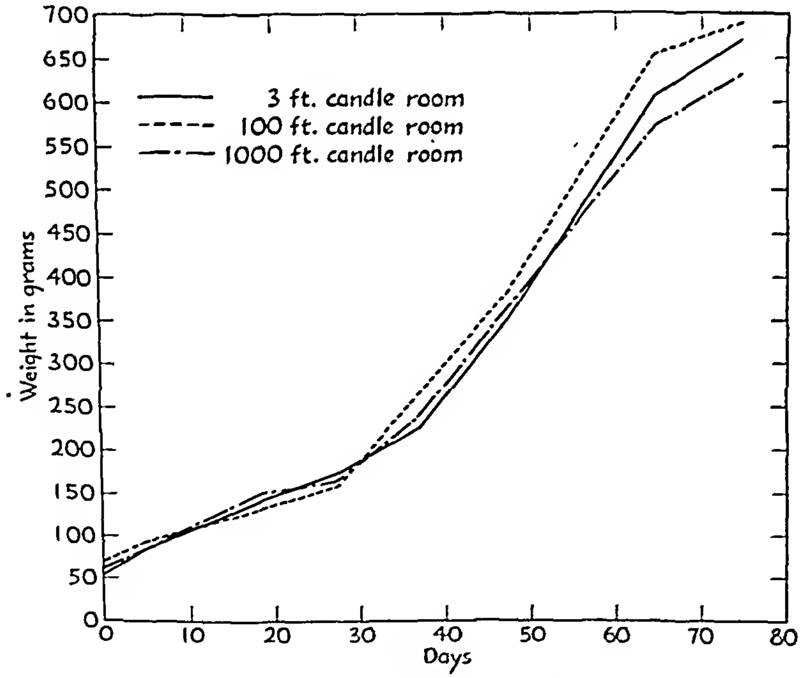

Chart X.—The growth curve of cockerels.

2. *Microscopic Studies.*—Sections from all organs were placed in 10 per cent formalin, sectioned, and stained with hematoxylin and eosin. Pieces of bone (the femurs were usually selected) were decalcified for microscopic study, and skin sections and skin biopsies were prepared from all animals. Examination of the prepared slides did not reveal any significant changes in the organs that one would not find in the study of control animals. Examination of the bones and the muscles of guinea pigs revealed findings similar to those previously described in experimental scurvy.[32] Skin biopsies taken from rabbits

in the experimental rooms revealed a few lymphocytes around some of the vessels of the corium. The number and the distribution of the lymphocytes did not vary according to the exposure of the animals to different intensities of light.

V. DISCUSSION

A. Health.—Physicians frequently advise increased exposure to artificial light and sunlight, but the evidence supporting the beneficial effects of light has been questioned (Clausen).[6] Although many clinical and some laboratory experiments call attention to the value of light, by which are most often meant rays of less than 3300 angstroms, most clinical and laboratory studies have shown that man and animals are able to continue in good health under restricted amounts of light if they are provided adequate diets.

Pearce and Van Allen[30] found evidence that the health of rabbits was not impaired by darkness, but that the rabbits exposed to constant light gained more weight than the unexposed group. From post-mortem observations they found no evidence that spontaneous lesions occurring in the experimental animals were related to the amount of light to which they had been exposed. Mackay[27] could find little evidence that infants exposed to mercury vapor quartz lamps grew faster or were in better health than a control group of children.

The anemic appearance of those living and working in poorly lighted homes and factories does not always indicate poor health. Little anemia has been found in animals working in mines.[16]. Rats placed in dark rooms were found to have a decreased number of blood platelets, but their general health remained good.[8] Laboratory studies on animals subjected to long periods of darkness have shown very little variation in the hemoglobin percentage or in the red cell count if the diet was adequate. Dogs placed in darkness for brief periods have shown an initial decrease in red blood corpuscle counts but a subsequent quick return to normal. Clinicians, on the other hand, have observed a rapid increase in hemoglobin and in red blood cells in anemic individuals exposed to solar and quartz mercury lamp radiations. Miles and Laurens[28] have shown that irradiations of anemic animals with ultraviolet rays are followed by an increase in the cellular elements and in hemoglobin; in this study, however, the changes were probably minimal and insignificant.

The general belief that increased quantities of light perhaps produce better health has led to the use of artificial light in the treatment of wounds and in the prevention of infections. Sunlight has been found to retard the growth of bacteria,[11] and ultraviolet radiation is advocated to reduce the frequency of infections in hospital operating rooms.[19, 23] Hill and Clark,[22] however, were unable to show that ultraviolet rays are beneficial to rats infected with pneumococci. In recent studies Buchbinder, Solowey, and Phelps[5] report the effect of various types and quantities of light on the growth of several strains of streptococci. They found bright sunlight to be a more powerful lethal agent on growing bacteria than daylight or artificial light. Their experiment indicates that the lethal action of light on bacteria is somewhat proportionate to the quantity of light and is related to the spectral quality of the light. The authors suggest that the suppression of the growth of bacteria by light may play an important role in the control of upper respiratory tract infections.

Fig. 1.—Litter mates from the 3, the 100, and the 1000 foot-candle rooms. Photograph taken five days following shaving.

Observers disagree concerning the effect of light on the healing of experimental wounds. Coburn and Cowles[7] found that experimental wounds of rats heal as well in darkness as in sunlight. On the other hand, Leo and Vaucher[26] and other experimenters as well have shown that wounds exposed to sun heal better than those covered. Crile[9] found artificial light from Mazda lamps a helpful adjunct in the treatment of wounds, but the beneficial effects in this instance could be due to the increased heat. Clausen,[6] after carefully considering controlled clinical studies and laboratory experiments, expressed doubt that light favors growth and promotes resistance to infections.

B. Growth.—Most investigators have found evidence that sunlight and artificial light stimulate the rate of growth of man and of experimental animals. This observation has proved of practical value in that chicks are often exposed to artificial light during their growth period.[29] In reviewing the reported experiments on the comparative rate of growth, one finds that investigators have usually compared the growth of animals in darkness or in minimal light devoid of ultraviolet rays to the growth of animals exposed to sunlight or to artificially produced ultraviolet rays.

Wade Brown[4] placed groups of normal rabbits in an experimental room in which neon tubes were added to produce 20 to 50 foot-candles of light. The rabbits in this room gained more weight than other rabbits grown in a dark room and more than rabbits grown in sunlight. In this experiment two groups of animals were exposed to ultraviolet rays while the quantity of light in the group exposed to sunlight is unknown. In comparable studies albino rats grown in darkness were found to grow more slowly than rats grown in sunlight,[25] and rabbits exposed to 425 foot-candle illumination were found to gain more than rabbits grown in dark rooms and in control rooms.[31] Bovie[3] noted that chickens that were raised in sunlight passed through a glass roof (probably devoid of ultraviolet rays) grew poorly compared to chickens raised in uninterrupted sunlight, and Borissow[2] found that dogs and rabbits grew better in adequate than in dim light.

Degkwitz[14] found that puppies raised in darkness appeared to be as healthy as control animals, but they showed a measured impoverishment in total ash, calcium, phosphorus, and magnesium. In a study of the growth of rats on deficient diets, Goldblatt and Soames[17] found that the rats irradiated with quartz mercury lamps grew more than the nonirradiated animals.

Northrop[28] calls attention to the fact that most reported experiments fail to show the effect of various quantities of light on the rate of growth of experimental animals. He exposed imagoes to varying intensities of light and discovered that there was no change in the rate of growth in intensities up to 600 meter candles, but he found that above that level the length of life of the imagoes decreased rapidly. After exposing flies to 10,000 meter candles, Northrop found their life span to be only 3.9 days compared to an average of 13.5 days for flies kept in the dark. He was unable to find evidence, however, that the absence of light in 230 generations had any effect on the duration of life or on the ability of the flies to resist infections. Higgins and Sheard[21] noted that frogs exposed to quartz mercury lamps were stimulated in the first twenty-four hours but that subsequently they showed a retardation of growth.

In a study of 100 healthy children Frank[16] was unable to correlate the growth periods with temperature, precipitation, or the amount of sunlight to which the children were exposed. Clinical studies are unsatisfactory because of the many factors beyond the control of the observer.

In our study we could find no evidence that an increased amount of light devoid of ultraviolet rays promotes growth. High levels of illumination, however, apparently produce no unfavorable influence on the health of experimental animals.

Fig. 2.—Litter mates from the 100 and the 1000 foot-candle rooms four days after shaving.

C. Eyes.—Artificial light rarely produces clinical symptoms or pathologic effects, but light improperly directed may be uncomfortable to the eye and in a few instances produce severe damage. Overstimulation produced by a constant bright light is thought to result generally in only physiologic fatigue and only very seldom in any detectable tissue damage.[12] The action of light upon the eye has been shown to be dependent on its wave length and on its intensity.[12] The shorter radiations, 3150 angstroms or less, are largely absorbed by the cornea or the lens while the radiations of the visible spectrum are more likely to be transmitted to the retina. Conjunctival and corneal lesions have been noted when the eye was exposed to strong radiations from artificial illuminants,

as mercury quartz lamps, or when the eye was exposed to reflected sunlight. Very long wave lengths may produce damage to all layers of the eye, the damage varying in degree with the intensity of the incident illumination and with the boundaries of transmission and absorption found to be different in different individuals. It is believed that the human eye is more transparent in the visible range than that of most nocturnal animals.

D. Sexual Maturity.—It is a common belief that natives in the tropics mature earlier than individuals living in temperate zones. In a careful clinical study Sundstroem[32] found that Anglo-Saxon girls in the tropics reached maturity at approximately the same age as girls in England; hence he believes that early maturity is a racial characteristic. Experimental studies, however, indicate that exposure to increased quantities of light produces early maturity and an increased size of the endocrine glands.

Fiske[15] raised groups of immature female rats in darkness, ordinary light, and continuous light. She noted that the immature female rats kept in light from birth or from the twenty-first day of life came into sexual maturity somewhat earlier than rats grown in ordinary laboratory light and much earlier than rats grown in complete darkness. In her group of males Fiske found at autopsy that the pituitaries, the testes, and the seminal vesicles were largest in the rats exposed to the maximum quantity of light. The difference in size was seen to be be greatest at 150 days; after 150 days the weights of the organs became comparable to the weights of organs from rats raised in dark rooms. Fiske points out that her study indicates a stimulating effect by light on the pituitaries of both male and female rats. Lack of light, in her opinion, favors a decrease in follicle-stimulating hormone and an increase in luteal hormone in the female. Similar conclusions were reached by Dawson[10] in a study of cats and by Benoit;[1] in the latter's study the testicles of immature ducks showed a rapid increase in size proportionate to the amount of illumination to which they were exposed.

In our study no careful observations were made to determine the relative time of development of maturity of animals exposed to different quantities of light. At post-mortem careful studies of the organs of the endocrine system were not made, but no gross deviations were seen in the various rooms.

E. Hair Growth.—An increased rate and amount of hair growth has been noted on the arms of attendants working in solariums. Brown[4] found that shorn albino rabbits exposed to neon lights showed an active proliferation of hair follicles, while rabbits living in the dark showed delayed, incomplete, or irregular growth. He attributed the effect to ultraviolet radiations.

Sundstroem,[32] after carefully measuring and weighing his clipped hair and nails, found that they grow 10 per cent more slowly in the tropics. He indicated that a slower rate of growth would be expected in all furry animals in warm climates.

We were able to confirm the findings of Brown[4] in that our shaved animals showed a more rapid hair growth when exposed to increased quantities of light. We did not, however, find a proliferation of hair follicles in the sections of skin taken by biopsy or obtained at autopsy. We believe the stimulus for increased hair growth may be central rather than peripheral.

F. Post mortems.—Careful post-mortem studies were reported by Pearce and Van Allen[31] of animals exposed to mercury quartz vapor lamps. The

organs of rabbits in the light rooms weighed less than those of rabbits in the control rooms. Small lesions noted in the organs were considered insignificant. Other studies of animals after exposure to light showed no differences in the organs of animals exposed to various quantities of light.

At the autopsies of the animals in our experiment gross inspection showed no differences in the organs of animals from the 3, the 100, and the 1000 foot-candle rooms. In a few animals small lesions were found in some organs, but they were irregular in distribution and did not appear to have any relation to the amount of light to which the animals had been exposed. Examination of slides prepared from the different organs showed them to be no different from the organs of control animals. One could conclude that varying quantities of light produce no obvious tissue damage.

VI. SUMMARY

Groups of rats, rabbits, guinea pigs, and chickens were exposed to different intensities of light in three experimental rooms. The animals received unlimited quantities of similar food in each room, and all were exposed to light an equal length of time daily. All animals were observed frequently to note any difference in behavior due to exposure to various amounts of light, and each animal was weighed frequently.

Animals were sacrificed at the end of an arbitrarily chosen experimental period if they had not died of an intercurrent illness. Autopsies were performed upon all animals, and tissues were obtained for microscopic study.

The health of the animals in the 3, the 100, and the 1000 foot-candle rooms was approximately the same. No differences in behavior of the animals could be detected, and the gain in weight of the various animals in the different experimental rooms was approximately the same. There was a noticeably increased rate of hair growth in animals exposed to higher intensities of light. Autopsy examinations revealed no unusual differences in the organs of animals exposed to various quantities of light.

UREASE ACTIVITY OF PROTEUS AND SALMONELLA ORGANISMS*

W. W. Ferguson, Ph.D., and A. E. Hook, Ph.D., Lansing, Mich.

One of the most important details of routine enteric bacteriology is the separation of nonpathogens from pathogens in the process of cultural elimination. It is usual for bacteriologists to transfer isolated colonies from differential plate media to triple or double sugar slants and judge from the reaction of the slants whether or not the organisms should be studied further. In the elimination process the greatest trouble to the worker results from those organisms which produce an alkaline surface on the slants, an acid butt and gas.

There are several possibilities as to the identity of such an organism. It may belong to the paracolon group, consisting of slow lactose- and sucrose-fermenting organisms with general coliform characteristics. It may belong to the proteus group whose members are nonlactose-fermenting, display a variable ability to ferment sucrose, and whose swarming tendencies are inhibited on differential media. It may belong to the genus Salmonella.

Among those working with animal fecal pathogens, the problem of separation of Proteus bacteria from Salmonella-like organisms is particularly burdensome because of the many Proteus strains encountered.

A test for swarming will prove of considerable value in discovering Proteus strains but, unfortunately, such a test is not entirely reliable. A small percentage of Proteus organisms have no ability to swarm; some Proteus strains are not highly motile and give an inconclusive reaction on two per cent agar. It has been our experience that some Salmonella strains on moist agar simulate the swarming activity of Proteus.

It is known that the urease activity of Proteus organisms and the nonurease activity of Salmonella provide a method of separating the commonly encountered members of the genus Proteus from organisms of the Salmonella group.

Numerous investigators have attested to the urea-decomposing ability of Proteus organisms. Of particular interest are the observations of Moltke[1] and of Rustigian and Stuart[2] who have made extensive studies on urea decomposition. Moltke examined 194 strains of maltose-fermenting and nonmaltose-fermenting strains of Proteus and found that all attacked urea. In 1941 Rustigian and Stuart[2] reported that all members of the genus except *Proteus hydrophilus*, *Proteus ichthyosmius*, and *Proteus bombycis* were capable of decomposing urea with formation of ammonia and subsequent production of alkali. They agreed with St. John-Brooks and Rhodes[3] that *Proteus hydrophilus* and *Proteus ichthyosmius* should be excluded from the genus. Rustigian and Stuart would also exclude *Proteus bombycis* from the genus for its inability to decompose urea.

The paracolon group of organisms has apparently not been studied for urease activity except by Ashworth[4] who tested 30 paracolon strains and found them unable to attack urea.

---

*From the Bureau of Laboratories, Michigan Dept. of Health.

Received for publication, May 5, 1943.

According to Bergey,[3] organisms of the Tribe Salmonelleae do not hydrolyze urea.

In a study on Salmonelliasis in infants, Hormaeche and Peluffo[5] described a simple medium consisting of Simmon's agar plus urea which they employed for differentiating Proteus and Salmonella organisms. They stated that the latter exert no action on the urea.

In our search of the literature we have been unable to find a comprehensive list of Salmonella strains which have been examined for urease activity. It is the purpose of this paper to supply such a list in the hope that other workers will be encouraged to use a test for decomposition of urea as an aid in enteric bacteriology.

MEDIA

Three media were used in testing the organisms listed in this paper.

Formula 1 was the synthetic medium of Rustigian and Stuart,[2] containing 2 per cent urea (Baker's. C.P.),* 0.01 per cent yeast extract (Difco), and M/15 primary and secondary phosphate buffers (Sorensen) in distilled water to give a final pH of 6.8. Sterilization was obtained by filtration through Seitz pads.

Formula 2 was devised in our laboratory. Its ingredients were as follows: 2 per cent urea (Baker's, C.P.), 0.1 per cent KH_2PO_4, 0.1 per cent K_2HPO_4, 0.5 per cent NaCl and 1.0 per cent ethyl alcohol (95 per cent). The pH was adjusted to 7.0. Sterilization was accomplished by filtration through a Seitz pad.

Both media were dispensed in 3 to 5 c.c. amounts in sterile 5 × ⅝ inch culture tubes.

Formula 3 was the solid medium of Ashworth[4] dispensed in the form of slopes. Its ingredients were: agar 2.5 per cent, distilled water, K_2HPO_4 0.1 per cent, $CaCl_2$ 0.01 per cent, Mg So_4. $7H_2O$ 0.01 per cent, NaCl 0.01 per cent, $FeCl_3$ 0.001 per cent, beef extract (Difco)† 0.5 per cent, brom thymol blue (1.5 per cent) 1 per cent, and urea 2.0 per cent. All ingredients, except urea, were dissolved in distilled water, and the base was sterilized by a temperature of 121° C. for twenty minutes. Sufficient 20 per cent urea solution was added to make a final concentration of 2 per cent urea.

METHOD OF TESTING

Organisms under test for urease activity were inoculated by loop from a 24-hour growth on veal infusion agar slants to the liquid media of Formulas 1 and 2 and to the slanted surface of Formula 3. After incubation for 24 hours at 37° C. the liquid media were tested for formation of $(NH_4)_2CO_3$ by the addition of several drops of brom thymol blue indicator. An intense blue color was accepted as evidence of the breakdown of urea with formation of alkali. The solid slants of Ashworth's medium (Formula 3) were observed for change in reaction 24 hours after inoculation of test organisms.

TEST ORGANISMS

Thirty strains of Proteus from animal and human sources were tested for urease activity. Their reactions in urea media are given in Table I. Seven of

*Rustigian and Stuart specified Merck's urea.
†Ashworth specified Lemco beef extract.

the cultures came originally from the American Type Culture Collection; however, of these, *Proteus hydrophilus* I and II did not possess the characteristics of this species. *P. hydrophilus* I gave the biochemical reactions of *Proteus vulgaris*, with the exception of rapid gelatin liquification; *P. hydrophilus* II resembled *Proteus mirabilis* in its reaction. Both organisms produced swarming on 2 per cent agar. The Proteus strains from animal sources were obtained from the collection of Mr. C. W. Darby of Michigan State College.

*American Type Culture Collection.
†Mich. Dept. Health Stock Culture Collection.

In Table II are recorded the reactions in urea media of thirty-eight strains of Salmonella obtained also from Mr. C. W. Darby. All strains came originally from Dr. P. R. Edwards of the University of Kentucky. Since these organisms had undergone several transfers since their initial typing, their Salmonella characteristics were checked by us. None of the organisms fermented lactose or sucrose, produced indol or liquefied gelatin. All were gram-negative and motile.

In Table III are recorded the reactions in urea media of thirty-seven Salmonella strains obtained from the stock culture collection of the Michigan Department of Health. Many of the organisms were identified by Dr. P. R. Edwards; the identity of the others was vouched for by the curator of stock cultures, Dr. Janet Bourn. All of the cultures were tested, however, for fermentation of lactose and sucrose, production of indol and liquefaction of gelatin,

gram staining qualities and motility. All of the organisms were Salmonella-like in their reactions.

In Table I it will be noted that all Proteus strains show evidence of decomposing urea with the exception of *Proteus ichthyosmius*. This organism produced a neutral reaction in Formula 1 and 2 and an alkaline slant surface in Formula 3, Ashworth's medium. Other Proteus organisms produced a deep blue color throughout Ashworth's medium.

289	E	*S. senftenberg* (5765-1)	Neutral	Neutral	Alkaline surface
293	E	*S. anatum* (M.C.M.1)	Neutral	Neutral	Alkaline surface
294	E	*S. new brunswick*	Neutral	Neutral	Alkaline surface
295	E	*S. give* (316)	Neutral	Neutral	Alkaline surface
372	E	*S. meleagridis*	Neutral	Neutral	Alkaline surface
373	E	*S. give*	Neutral	Neutral	Alkaline surface
288	Additional	*S. kentucky* (18)	Neutral	Neutral	Alkaline surface
291	Additional	*S. worthington* (Minn. 39)	Neutral	Neutral	Alkaline surface
358	Additional	*S. carrau*	Neutral	Neutral	Alkaline surface
298	Additional	*S. minnesota* (Minn. 2)	Neutral	Neutral	Alkaline surface
359	Additional	*S. onderstepoort*	Neutral	Neutral	Alkaline surface
356	Additional	*S. aberdeen*	Neutral	Neutral	Alkaline surface
357	Additional	*S. poona*	Neutral	Neutral	Alkaline surface

It was conjectured that the reaction of *P. ichthyosmius* in Ashworth's medium was due to the breakdown of nitrogenous substances in the meat extract component. All of the Proteus strains were therefore inoculated onto Ashworth's medium minus urea and were found with no exceptions to produce

alkaline slant surfaces but no reaction in the butt. Uninoculated controls were unchanged by incubator temperature.

The possibility of misinterpretation of reactions on this medium was undoubtedly realized by Ashworth[4] who cautioned that only the full range of brom thymol blue (on the alkaline side) denotes a positive result.

In the media of Formulae 1 and 2 none of the seventy-five Salmonella cultures listed in Tables II and III gave any evidence of attacking urea. In Ashworth's medium none of the Salmonella cultures gave the deep blue coloration throughout the slant which characterized the growth of Proteus strains on this medium. However, 67 strains produced an alkaline surface. It was considered that these organisms, like *Proteus ichthyosmius*, were incapable of decomposing urea but did produce an alkaline reaction from the breakdown of the meat extract of Ashworth's medium. When the same Salmonella strains which produced an alkaline surface on the urea medium were grown on Ashworth's medium minus urea, they again produced alkali on the surface of the slope.

Rustigian and Stuart[2] tested the reaction of Proteus strains in their medium with and without urea and established that alkalinity resulted only when urea was present. Formula 2, with and without urea, was tested by us with Proteus and Salmonella cultures. An alkaline reaction resulted from the growth of Proteus only when urea was present; no change in the pH of the medium was produced by growth of Salmonella cultures whether or not urea was present.

DISCUSSION

The reactions of thirty Proteus and seventy-five Salmonella strains in urea media were unusually clear-cut. Only *Proteus ichthyosmius* of the thirty Proteus strains failed to decompose urea. None of the Salmonella cultures showed evidence of decomposing urea.

It is true that all of the organisms tested by us were stock cultures or had lived for several generations on artificial media. In addition to these, approximately fifty newly isolated Salmonella strains have been tested for urea decomposition in the laboratories of the Michigan Department of Health during the last eight months. None of the Salmonella cultures attacked urea.

It will not be surprising if one or more Salmonella of the 107 species listed by Kauffmann[7] are found capable of attacking urea. Some strains of *S. Eastbourne*, it will be remembered, vary from the Salmonella characteristics by producing indol; three species of Salmonella liquefy gelatin and a variant of *S. anatum* has been described which ferments lactose. However, the results in this paper indicate that urea-decomposing strains of Salmonella will rarely, if ever, be encountered.

Of the three urea media used our inclination is in favor of the liquid medium of Rustigian and Stuart, or Formula 2. Ashworth's solid medium, while convenient to use, may very well give misleading results to one who is unfamiliar with its reactions with and without urea.

SUMMARY

Of thirty strains of Proteus, *Proteus ichthyosmius* only failed to decompose urea.

None of seventy-five strains of Salmonella showed evidence of attacking urea.

A test for urease activity is recommended as a routine procedure for separation of Proteus and Salmonella organisms.

THE CEPHALIN FLOCCULATION TEST IN JAUNDICE*

PAUL A. KIRSCHNER, M.D., AND STANLEY I. GLICKMAN, M.D., NEW YORK, N. Y.

IN 1938 and 1939 Hanger[1, 2] reported a new laboratory test employed as a diagnostic measure in jaundice of various types. It was an empirical reaction, of incompletely understood mechanism, which depended on the flocculation of a cephalin-cholesterol emulsion in the presence of the serum of patients with active parenchymal disease of the liver. In a series of over 900 normal individuals there was only one weakly positive reaction, while in catarrhal jaundice and acute hepatitis it was found to be positive at the height of the disease. The reaction in obstructive jaundice was negative or only very weakly positive, the latter occurring in cases of prolonged obstruction and/or acute associated hepatitis. The test was found to parallel the activity of the pathologic process in cirrhosis. Hemolytic jaundice gave negative results. However, Hanger[1] listed a number of miscellaneous conditions with or without jaundice, including such diseases as subacute bacterial endocarditis, various types of pneumonia, nephritis, and other infections in which the test was positive in a goodly proportion of instances. Nevertheless, if the clinical picture, corroborative laboratory data, and pathologic findings were carefully studied, and particularly if the test was confined to jaundiced individuals, there was a good indication that the cephalin flocculation reaction was a reliable index of the degree and type of active parenchymal disease of the liver.

In 1940 Hanger and Gutman[3] published the clinical, chemical, and pathologic findings in cases of icterus following arsphenamine therapy. These observers had previously noted that in a minority of patients with postarsphenamine jaundice the cephalin flocculation test gave negative results and that the serum phosphatase activity was elevated, indicating an obstructive intrahepatic type of icterus rather than the usual parenchymatous type. This was confirmed by pathologic examination. It was on the basis of these studies that the cephalin flocculation test was found to have selective value in differentiating obstructive from nonobstructive jaundice.

Since then, several observers have reported their results with the flocculation test, and although their findings occasionally vary from those of Hanger, they all accept the test as a dependable aid in the differential diagnosis of jaundiced conditions. Pohle and Stewart[4] found in a series of 141 patients with hepatic or biliary tract disease that the reaction was positive in varying degrees in most instances. However, they regarded a one- or two-plus reaction as positive. They were impressed with the sensitivity of the reaction in detecting degrees of liver damage rather than its selectivity in distinguishing

*From the Medical and Surgical Services of the Mount Sinai Hospital.
Received for publication, September 6, 1943.

obstructive from nonobstructive jaundice. In their hands false positive reactions were rare. Rosenberg[5] also emphasized the delicacy of the test, for he considered any positive reaction (even as slight as plus-minus) as indicative of liver disease. In employing the procedure as a means of separating obstructive from parenchymatous jaundice, he based his conclusion on the degree of flocculation, rather than on its presence or absence. Nadler and Butler[6] agreed in general with the observations of Hanger. Of particular interest is their finding that four cases of jaundice following arsphenamine therapy all gave negative reactions, thereby confirming the observations of Hanger and Gutman. They employed a cephalin which was obtained from the same source as that used in the present study and suggested that the reagent used by Pohle and Stewart was too sensitive.

Mateer, Baltz, Marion, Hollands, and Yagle[7] reported an extensive comparative laboratory evaluation of hepatic and biliary tract disease which included the cephalin cholesterol flocculation reaction. They noted that the test was at once specific and sensitive and recommended it without reservation. However, since their cases are not grouped from the standpoint of "medical" versus "surgical" jaundice, their results are not strictly comparable to those included in this paper. Nevertheless, they pointed out that although Hanger held that "unripened" cephalin (i.e., that which is not allowed to oxidize by lengthy exposure to air) is more sensitive and more liable to give false positive reactions, the reverse held true in their experiences. Specifically, in 40 normal controls there were 5 one-plus reactions after forty-eight hours with the "unripened" material, while the use of the "ripened" substance gave several times as many positive results, some even two-plus reactions. A more recent report[8] relates the relative value of the commercial substance made by the Difco Company of Detroit (that used in this work), namely, that a one-plus reaction per se had no positive significance.

The present study includes 154 cases of jaundice observed on the wards of the Mount Sinai Hospital from October, 1941 to April, 1943. They have been grouped under the headings of obstructive and hepatocellular jaundice, with particular reference to the differentiation of medical and surgical conditions. The sensitivity of the cephalin used (Difco product) coincided with that in Dr. Hanger's laboratory, and the methods employed in the performance of the test were in accord with his directions. The results of the reaction have been designated as 0, 1 plus, 2 plus, 3 plus, and 4 plus, and readings were made after twenty-four and forty-eight hours. Although the 24-hour reading was considered more sensitive, the interpretation of the test was based upon the 48-hour reading, because this was found more clear-cut and reliable. For the sake of reliability and in view of other clinical, chemical, and pathologic findings, the cases giving a 1-plus reaction were interpreted as negative. Dr. Hanger had suggested that a 1-plus reaction had no definite significance in relation to parenchymatous disease, unless this was noted during recovery or in cirrhosis. In a large number of cases the test was done several times in the course of the disease, and some of the repeated determinations indicate the variation correlated with the dynamics of the pathologic process. The proved cases were confirmed by post-mortem examination or surgical exploration.

The results are summarized in Tables I and II.

DISCUSSION

In the cases of obstructive jaundice, the cephalin flocculation test showed an accuracy of 83 per cent. It would appear that the problem of differential diagnosis of "medical" vs. "surgical" jaundice was nearer a solution by this reaction. Unfortunately, as will be shown later, a fairly large number of instances of parenchymatous jaundice gave negative reactions. At any rate, our interpretation of the 1-plus reaction as negative appeared to be well grounded.

In cases of "infectious" hepatitis the reaction was positive in about two-thirds of the cases. Although the sensitivity of the test does not appear to be remarkable, its reliability when positive is great, for whenever a 3-plus or 4-plus reaction occurred, the diagnosis of parenchymatous liver disease was confirmed

by chemical or pathologic data. Only rarely did a case of obstructive jaundice give a positive reaction, and then only weakly positive such as 2 plus.

The type of toxic reaction to organic arsenical therapy described by Hanger and Gutman,[3] i.e., an intrahepatic obstructive icterus, was encountered in 4 cases. All were in individuals who received only two or three doses of the arsenical (in these instances, neoarsphenamine). The onset of icterus was sudden and in 2 cases the jaundice was prolonged. It should be noted that in Nadler and Butler's[6] cases as well, the flocculation test was negative in all instances.

In cirrhosis, the cases exhibiting evidence of active liver disease as evidenced by jaundice, as well as other stigmata of hepatic insufficiency yielded positive reactions in only half of the cases. In an additional three cases not tabulated because jaundice was absent, two were 0, and one was 1 plus.

SUMMARY AND CONCLUSIONS

1. By means of the cephalin flocculation test 164 assorted cases of jaundice were studied over a 22-month period, with interest directed toward differentiating obstructive from nonobstructive icterus.

2. Of 75 cases of obstructive jaundice, 62 were "negative."

3. Of 58 cases of hepatitis, 20 were negative and 38 were positive.

4. Of 4 cases of postarsenical icterus, all were negative.

5. Of 17 cases of cirrhosis with jaundice, 12 were positive.

6. In 3 cases of hemolytic jaundice, the reaction was negative in 2, positive in 1.

7. In our laboratory, the cephalin flocculation test reached its highest degree of accuracy in the obstructive jaundice group, but paradoxically was more reliable in the hepatitis group because false positives were a rarity.

8. To our mind the 1-plus reaction is of no significance in distinguishing obstructive from nonobstructive jaundice.

9. In general, the cephalin flocculation test may offer assistance in the differential diagnosis of jaundice. However, in our hands its accuracy did not concur with the results published by Hanger.

We wish to express our gratitude to the Difco Company of Detroit for their supplies of cephalin and to the Eli Lilly Company of Indianapolis for merthiolate.

OBSERVATIONS ON THE INGESTION OF METHYL CELLULOSE AND ETHYL CELLULOSE BY RATS*

WILHELM DEICHMANN, PH.D., AND SYLVAN WITHERUP, B.S., CINCINNATI, OHIO

BECAUSE of the potential usefulness of methyl and ethyl cellulose as thickening and binding agents in the pharmaceutic and food industries, the possibility that they might have deleterious effects was investigated by feeding them to rats over a considerable period of time.

Methyl cellulose[1] is a white, fibrous, cellulose ether, soluble in cold water but insoluble in hot water and in most organic solvents. Heating causes most aqueous solutions of methyl cellulose to coagulate, but cooling and stirring restores them to their original smoothness and fluidity. Solutions of the compound are colorless, odorless, and tasteless. Ethyl cellulose,[2] also a cellulose ether, is insoluble in water but soluble in most organic solvents. Its solutions are colorless and odorless.

Acknowledgment is made to the Dow Chemical Company for the financial support of the investigation and for the supply of the materials in the form of Methocel (Lot M-368, viscosity 1500 centipoise) and Ethocel (Lot 2467, viscosity 20 centipoise).

GENERAL EXPERIMENTAL PROCEDURES

Young albino rats, male nad female, bred in this laboratory and all of approximately the same age and weight, were divided into 3 groups of 80, to be fed the two cellulose ethers and the control diet, respectively. They were caged in groups of twenty. The food was supplied in baskets of wire screening, and the drinking water, in bottles fitted with glass tubes, the quantities consumed being recorded weekly. Experiments were started in July and terminated in the following March, at which time a representative number of animals from each group was killed and examined for gross and microscopic tissue changes.

PREPARATION OF FOOD AND WATER

Eighty grams of methyl cellulose were wet with hot water, cooled to room temperature, and stirred until nearly smooth; then one liter of cold water was added, and after the mixture had been kept about twenty-four hours in the refrigerator, the whole was diluted to 1500 c.c. with water, mixed, and added to 10 kg. of Purina Fox Chow pellets. Thus 10 Gm. of the dried food contained 80 mg. of methyl cellulose (8,000 parts per million). The drinking water was prepared so as to contain 10 Gm. of methyl cellulose in one liter of water (10,000 parts per million).

Ethyl cellulose (120 Gm.) was dissolved in 3 liters of 95 per cent ethyl alcohol and added to 10 kg. of Purina Fox Chow. After the alcoholic solution had

soaked in, the pellets were heated for two days at 70° C. in order to expel the solvent. (Analyses proved that the alcohol had been expelled except for insignificant traces.) Ten grams of this food contained 120 mg. of ethyl cellulose (12,000 parts per million).

RESULTS

Group 1.—The 80 rats in this group were given both food and water containing methyl cellulose. The consumption of food varied from 13 to 19 Gm. per day, and the daily intake of water ranged from 25 to 34 c.c. so that the average total daily intake of methyl cellulose was about 436 mg. per rat, 125 mg. being ingested with the food and 311 mg. in the drinking water.

Group 2.—The 80 rats in this group ingested from 14 to 18 Gm. of food per day, the daily intake of ethyl cellulose being about 182 mg. per rat. These animals had free access to uncontaminated drinking water.

Group 3.—The consumption of food and water by the 80 control animals varied within the limits recorded in the case of Groups 1 and 2 above.

Fig. 1 portrays the weight changes that occurred in each group as a whole. The differences among the three groups in this respect were manifestly insignificant. No other evidences of differences in the behavior or well-being of the animals in the several groups were noted.

SUMMARY AND CONCLUSIONS

Eighty rats were given methyl cellulose in their food and drinking water over a period of eight months, and the same number were given ethyl cellulose in their food for a corresponding period. The daily ingestion of quantities of methyl cellulose amounting to about 0.44 Gm. per rat or of ethyl cellulose amounting to about 0.18 Gm. per rat produced no signs of illness. The consumption of food and water as well as the gain in weight by these animals was normal. No evidence was found of significant gross or microscopic abnormalities in the tissues of the animals. It is concluded that the feeding of methyl and ethyl cellulose in these concentrations is harmless to rats.

LABORATORY METHODS

GENERAL

AN INK-WRITING FINGER PLETHYSMOGRAPH*

HAROLD V. RICE, M.D., PH.D., WINNIPEG, CANADA

VARIOUS forms of finger plethysmograph are in use, employing photographic methods or using photoelectric cells. At least one form of ink-writing plethysmograph has been described,[1] though the data concerning its construction are not available. The present method has the advantage of being relatively inexpensive, has proved exceedingly simple and reliable to use, and can be made by anyone with a moderate knowledge of electronics. The advantage of an ink record of volume changes is obvious, since it makes possible observations over prolonged periods of time and provides a tracing which can be examined immediately, without the trouble and expense of developing it, as with the photographic method. The apparatus herein described also has the advantage that, since the plethysmograph chamber on the finger is connected to the recording unit only by fine flexible leads, slight movements of the hand do not tend to displace the plethysmograph relative to the finger. The plethysmograph is free in other words to move more or less as the hand moves.

The metal plethysmograph chamber (Fig. 1) is attached to a metal plate shaped to fit the palm and loosely bound to the palm by adhesive or spring clips at the edges. The latter method avoids obstruction of the venous return from the fingers. The distal end of the plethysmograph chamber is closed off with a slack condom rubber diaphragm. At the distal end of the chamber a bracket extends at right angles. This is made of metal, and being attached to the metal chamber is therefore at body or ground potential. Several parallel metal plates (4 to 8) are attached at right angles to this bracket. A moving arm is suspended on an insulator at the outer end of this bracket and is fitted also with parallel metal plates, which slide between the metal plates of the bracket without touching them, thus forming a variable condenser. The moving arm and its plates are made of aluminum foil (#35 gauge) for lightness, weighing only 4.0 Gm. Strength is obtained by flanging the edges where necessary. Movement is imparted to the movable arm by the condom diaphragm through a connecting pin. A gentle spring holds the pin constantly in contact with the diaphragm.

The finger is inserted into the plethysmograph with the "adjustment capsule" removed (cf. Fig. 1). An airtight seal is obtained simply by pressing

*Department of Physiology, University of Manitoba.

vaseline between the edge of the plethysmograph and the skin. The "adjustment capsule" is then slipped onto the "stem." The adjustment screw is then tightened, thus depressing the thick rubber diaphragm beneath it, until the condom diaphragm is displaced outward to bring it into the mid-zone of its movement range. The two lead wires are then connected and the record may be taken. The preparations for a tracing take about a minute.

A calibrator is built into the plethysmograph. It consists simply of a thick rubber diaphragm, which is displaced by movement of a lever. It permits quick calibration of each tracing to be made. The calibrator must first be standardized against a known standard, the one in use having a displacement of .06 c.c.

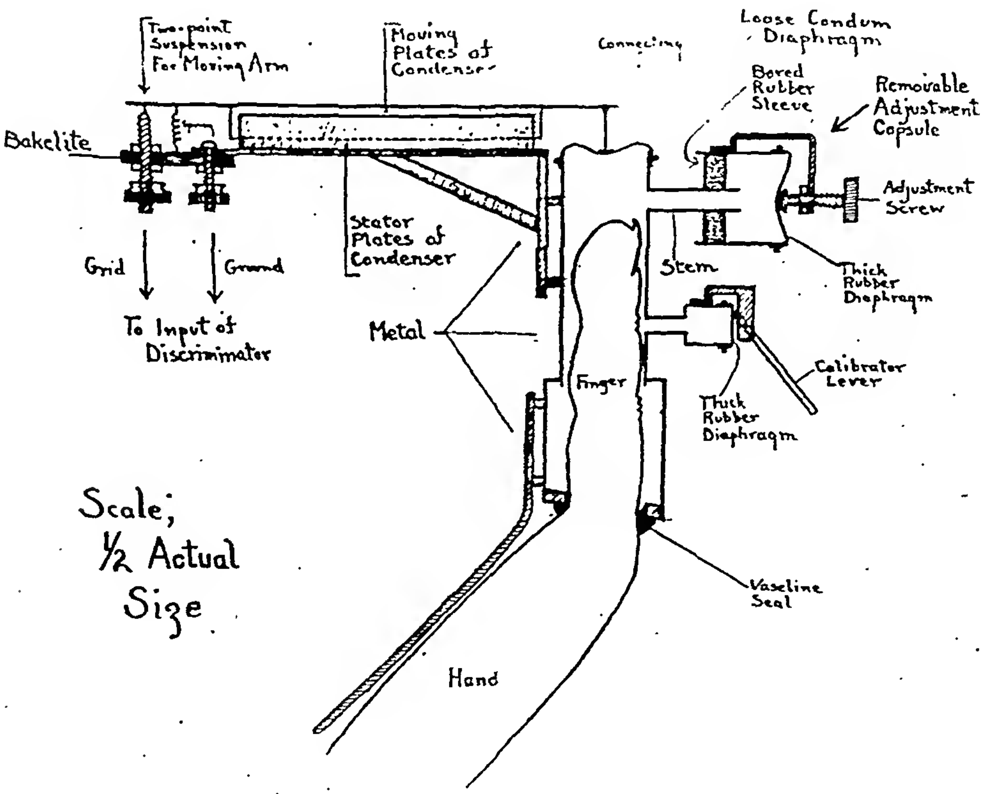

Fig. 1.—Scale diagram of finger plethysmograph.

The changes in finger volume are converted into changes of voltage which operate the recorder. The electrical circuit consists of a frequency discriminator which converts changes in frequency in an oscillator to voltage changes, which are amplified. Two oscillator circuits, A and B (Fig. 2), are tuned to beat against each other. The resulting beat frequency is fed into two mixer tubes in parallel. Mixer tube A passes its output into a band-pass transformer tuned to 175 kilocycles, and mixer tube B passes its output into a band-pass transformer tuned to 172.5 kilocycles. When the frequency of oscillator A is

tuned by its condenser C_1 to beat with oscillator B to produce a beat of 175 kilocycles, the maximum flow of current is produced through detector circuit A, and a maximum voltage drop is produced across resistor R_5. At this frequency the band-pass circuit B does not respond, and no current flows through detector circuit B. Consequently no potential difference is developed across

Fig. 2.—Schematic diagram of frequency discriminator and amplifier.

resistor R_6, so that points X and Z are at the same potential. Since there is a voltage drop across resistor R_5, point Y is positive with respect to point X and therefore also with respect to point Z. As a result the control grid of driver stage A becomes positive with respect to ground. As the potential of the control grid of driver stage B is not changed, the direct-coupled push-pull amplifier is thrown off balance, and moving coil L_8 connecting the two plates of the 6L6G output tubes is displaced. If oscillator A is tuned by its condenser to produce

a beat of 172.5 kilocycles, the band-pass circuit B responds to its maximum, and a maximum voltage drop occurs this time across R_6, making X negative to Z. Since no response is induced in band-pass circuit A at this frequency, no voltage drop occurs across R_5, and Y and X remain at the same potential. Y is thus negative with respect to Z, in consequence of which the control grid of driver A becomes negative with respect to ground, while the potential of control grid of driver B remains unchanged. The push-pull direct-coupled amplifier is put off balance in the opposite direction, and moving coil L_8 is moved in the opposite direction. When oscillator A is tuned to give a beat midway between 172.5 and 175 kilocycles, both band-pass circuits respond equally and an equal voltage drop occurs across R_5 and R_6. Y and Z are then at the same potential so that the control grid of driver A remains at ground potential, and the amplifier remains balanced. From this position of balance any change of frequency of oscillator A will change the beat frequency so that more current is induced in either band-pass circuit A or B.

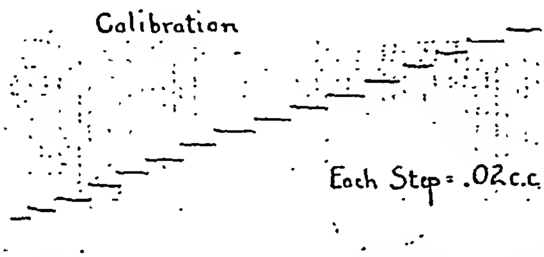

Fig. 3.—Record of successive increments of .02 c.c. into the plethysmograph from a pipette, showing the linearity of the response. Greater sensitivity can be obtained when desired.

When the plethysmograph is connected to the discriminator, the fixed plates of its variable condenser are connected to ground and the moving plates to the grid of oscillator A. By means of variable condenser C_1 the beat frequency is adjusted until the writing point connected with moving coil L_8 is brought to the mid-position. The correct setting of the condenser is easily found, for by turning it either way from the point of central adjustment, the writing lever should move an equal amount, first to one side, then to the other, as the movement of the condenser is reversed. Any variation of the position of the moving plates of the plethysmograph condenser, induced by changes of finger volume, causes a change in the frequency of oscillator A and therefore of the beat frequency and thus displaces the recording pointer.

In order to reduce undesirable interaction between the two oscillators, oscillator A is capacitatively coupled to the mixers and oscillator B is inductively coupled. The use of two mixers in parallel simplifies alignment of the band-pass circuits since they are then independent. Each circuit can be aligned separately without upsetting the alignment of the other. A separate high-voltage supply is used for the discriminator circuit. Condenser C_2 is used to tune the mixers to give the maximum response. The variable grid bias on only one of the 6SJ7 tubes, permits the voltage at the plates of the 6L6G tubes to be equalized. This is important, since with the direct coupling of the drivers to

the output tubes, slight inequalities in function of the driver tubes might cause serious imbalance in the output tubes. It must be noted also that the plate supply of the output stage is all above ground and requires special care in wiring and mounting. Since the heaters of the 6L6G tubes are also above ground, this heater winding is not center tapped. Condenser C_0 is to eliminate an A.C. component in the output. It should be a paper condenser to avoid leakage through it from the plate supply of the drivers which would tend to make the grids of the output tubes positive. The recording pointer is activated by a moving coil, suspended by springs in a dense magnetic field. The battery plate supply of the driver stage may be replaced by another power source. A potentiometer is used in the grid of the driver stage to control the gain of the amplifier. In order to vary the sensitivity of the variable condenser on the plethysmograph and to make it of service whether small or large changes of volume might occur, some of the plates of the stator can be removed in a moment from spring clips that hold them in place.

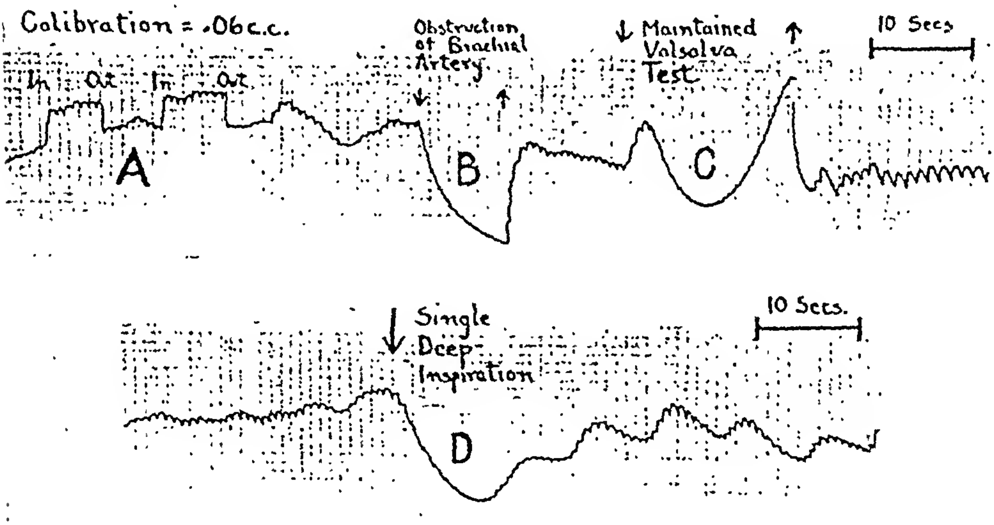

Fig. 4.—Tracings taken with the finger plethysmograph.

A, Calibration with .06 c.c. displacement, using the calibrator built into the plethysmograph.

B, Passive vasoconstriction due to obstruction (by pressure) of the brachial artery. Prompt return of volume on release of pressure.

C, Biphasic response with maintained forced expiration against the closed glottis. Prompt return of volume when forced expiration stopped, followed by large pulse waves.

D, Active vasoconstriction due to a single deep inspiration. Subsequent undulations due to respiratory movements.

Vasoconstriction or reduced finger volume causes downward movement of the recorder. Vasodilatation or increased finger volume causes upward movement of the recorder.

A calibration of the plethysmograph made by injecting successive volumes of 0.02 c.c. air into the chamber is shown in Fig. 3, indicating the linearity of the response.

It should be pointed out that the type of variable condenser on the plethysmograph does not lend itself to rapid volume changes. Frequency calibration curves have not been done, since the apparatus is designed primarily to record the slow volume changes of a finger due to changes of vascular control.

It is possible that some distortion would occur in the recording of the pulse curves, especially in the sharply rising phase. But such distortion, if present, would not lessen the reliability of records of the slow volume changes.

The actual apparatus in use was made from odd materials at hand. More recent types of tubes, etc., could profitably be substituted if available. Maximum voltage variations between Y and Z (Fig. 2) were about 20 volts. Maximum excursion of the pointer is about 6 cm. with a lever ratio of approximately 6 to 1.

Typical records of finger volume changes are shown in Fig. 4.

MACHINE-ROLLED STOPPERS FOR CULTURE TUBES

Harold W. Batchelor, Ph.D.,* Wooster, Ohio

Much of the loss of materials and of the labor required to make stoppers for culture tubes may be avoided if machine-rolled stoppers that can be used repeatedly are made by a lathe such as herein described.

The tongue of the stopper-spindle (1), two inches long, tapers from one-eighth of an inch at the shoulder to one-sixteenth of an inch at the tip. A second spindle for making hollow stoppers for use with pipettes is eleven sixty-fourths and ten sixty-fourths of an inch in diameter at the shoulder and tip respectively. The spindles, driven by a one-fortieth horsepower motor, are mounted on the motor shaft by means of a work arbor and chuck (2). A 20-gauge steel channel with flared flanges comprises the stopper forming table (3). The right half of the channel web, raised an amount equivalent to one thickness of the sheet steel, forms the tapered end of the stopper. A slot is cut in the left-hand flange to permit the spindle to function. The forming table is secured with two machine screws (4), near the left side, to an inclined forming table support (5). Two setscrews (not visible), mounted from below at the right side of the forming table support, bear on the under side of the forming table and permit tapering the smaller end of the stopper to any desired taper.

The stopper's diameter is controlled by an adjustable mechanism mounted on the upper end of the forming table support (5). The mechanism consists of a short channel (6), two setscrews (7), two flat springs (8 and 9), and a spring support (10). The lower setscrew (only partially visible) presses against the lower side of spring (8), one end of which is fixed to the lower side of the spring support (10). The angle of the latter conforms with the angle of the forming table support. The upper setscrew (7) presses against the upper side of a slightly bent flat spring (9), one end of which is free but whose

*Microbiologist, Ohio Agricultural Experiment Station.

FIG.

FIG. 2

FIG. 3

other end is attached to the free end of spring (8). These two springs hold the forming table firmly against the spindle or cotton as the stopper is being rolled. Passing through, and tightly fitting into, the lower end of the forming table support runs a shaft (11), to whose left end is attached a coiled returner spring (12). Brass bearings mounted in walnut pillow blocks (13) support the shaft. Two adjusting studs (14) control the right and the left positions of the forming table support. A base, eight inches by sixteen inches, supports the entire mechanism.

The motor is started by means of the toggle switch (15), the spindle is moistened with water from (16), approximately the correct amount of cotton or other fibrous material is touched to the spindle, and the stopper is quickly rolled. The handle of the stopper may be painted or sprayed with a tinted plastic in solution (17), and the stopper may then be removed by pushing the forming table support to the right by means of post (18). Small stoppers may be made if a small-sized forming table is clamped to the right side of the larger forming table. Some stoppers made by the lathe are shown in Fig. 3. Stoppers have been made of absorbent and nonabsorbent cotton, fiber glass, and even steel wool. The latter two are only curiosities at the present time. The most satisfactory material yet used is a combustion-resisting DuPont cellulose acetate product known as 3-F Continuous Filament Batting. Being in an experimental stage, this material is not yet available commercially.

A NEW METHOD OF COUNTING PLASMODIA IN AVIAN MALARIA INFECTIONS*

HARRY BECKMAN, M.D.,† AND JANE SMITH, M.T.
MILWAUKEE, WIS.

THE best known and probably most used method of counting plasmodia in the peripheral blood in avian malaria infections is that in which the result of the count is recorded in terms of plasmodia per 10,000 erythrocytes. One of the forms of this "standard" method consists in counting the plasmodia seen in 1,000 erythrocytes and simply multiplying by 10; one counts erythrocytes up to 1,000 "in the head" while simultaneously recording plasmodia with pencil marks on a pad; or one counts the plasmodia on a pad or "in the head" and records erythrocytes on a mechanical counter; or one counts the erythrocytes first, notes on the verniers of the mechanical stage the limits within which the count was made, and then goes back and counts the plasmodia within these limits. In any case the resulting plasmodial count is multiplied by 10 and recorded as organisms per 10,000. We have not been able to satisfy ourselves that our counts are notably accurate when made in any of the above ways.

---

*From the Department of Pharmacology, Marquette University School of Medicine, Milwaukee, Wis.
Received for publication, March 18, 1943.
†Partially supported by an Eli Lilly and Company grant.

A variant of the "standard" method consists in averaging the counts of 5 fields and dividing this number into 1,000 to determine the number of fields in which plasmodia must be counted in order to record the organisms per 10,000 (after multiplying by 10, of course); or one may divide directly into 10,000 and then make an actual count of the resultant very large number of fields. Working as we do, with a 92x objective and a 10x eyepiece, we find fields ideal for counting (i.e., well filled but with the erythrocytes not touching) to contain 90 to 100 cells; this would require us to see only 10 or 11 fields in order to obtain our 1,000 cells; we think this too few, but on the other hand to examine the 100 to 110 fields, which would be required to complete the count of 10,000, would certainly not be practicable. Another reason for our inability to be entirely satisfied with this method is that it assumes an almost perfect uniformity of smearing, which we are not certain that we invariably achieve.

The only other variant of the "standard" method with which we are familiar is to apply in each separate instance a formula by which to determine the number of erythrocytes to be examined, if the plasmodial count is to have an error of no more than 10 per cent. Gingrich[1] states this formula as follows: $N = 45.494 \frac{I-P}{P}$ in which N = the number of erythrocytes to be counted, P = the number of parasites per sample unit, and I = the sample unit (10,000 erythrocytes). At the present time, when a very large number of smears must be examined daily in all laboratories, we feel obliged to think of this method as having only academic interest.

Several years ago the senior author[2] offered a method which differed entirely from the "standard" method or any of its variants: A fixed number of plasmodia were counted, and then the count was recorded in terms of the time required to make it. This method, which enables one very simply to record degrees of infection as +, 2+, 3+, 4+, and 5+, served us in a practical way for a time, but it failed to prove sufficiently delicate to reflect slight differences in the antimalarial activities of the newer compounds which are being studied nowadays. We have therefore devised, and have been using with satisfaction for more than a year (i.e., in many hundreds of infections), the method now to be described.

DESCRIPTION OF OUR NEW METHOD

Using a 92x oil immersion objective and a 10x eyepiece, we give the slide a hasty examination to find an area in which we can range through a good many fields without encountering excessively wide variations in the thickness of the smear. Then the count is made:

The method consists in counting the number of organisms seen in three minutes of a *standardized type of search*. One starts the stop watch and then looks at every erythrocyte in the field. This is important; the whole field is not just quickly scanned and the number of plasmodia present noted, but instead every erythrocyte is looked at and the number of plasmodia seen during the course of this examination of the erythrocytes is counted. Then one turns to the next field and continues to examine erythrocytes and count plasmodia this way until the three minutes have elapsed. The total number of plasmodia counted in the three-minute period is then recorded as the index of the infec-

tion on that day. The watch is not stopped as one shifts from field to field, but it is stopped when glancing at it to determine the amount of elapsed time.

Two variants of the above are employed to make the method applicable to all the situations arising. (a) A negative slide is treated just as is a positive one; i.e., all erythrocytets are looked at in all the fields which are viewed in the three-minute period, but if a plasmodium is not encountered, the slide is simply recorded as negative. (b) If, in the examination of an apparently negative slide, a plasmodium is finally encountered before the three minutes have elapsed, the watch is stopped and reset at zero, and one starts over on a fresh count of three minutes beginning with this organism as plasmodium 1. This latter situation arises almost exclusively only on the first day of infections, for practically always on the days thereafter there is a sufficient abundance of organisms so that one is quickly able to find a field containing at least 1 plasmodium with which to begin the count.

COMPARISON OF METHODS

Table I presents the data from a study of 5 birds infected with our 3H2 strain of *Plasmodium cathemerium*, each bird being represented by a smear obtained at 9:30 A.M. on the first five days of its infection. The counting by our method was done on the dates as shown during a period when these birds

were being employed as untreated controls in a routine study. The counting by the "standard" method was done at a later time, thus increasing the validity of the comparison, since it is highly unlikely that the same fields were selected for study in both instances. It will be seen that in using our method the count on the first day always required more than three minutes, since some time was employed in finding the first organism; but the counts of the succeeding days required only the arbitrary three-minute period. In the "standard" counts the time required varied from four minutes and twenty seconds to five minutes.

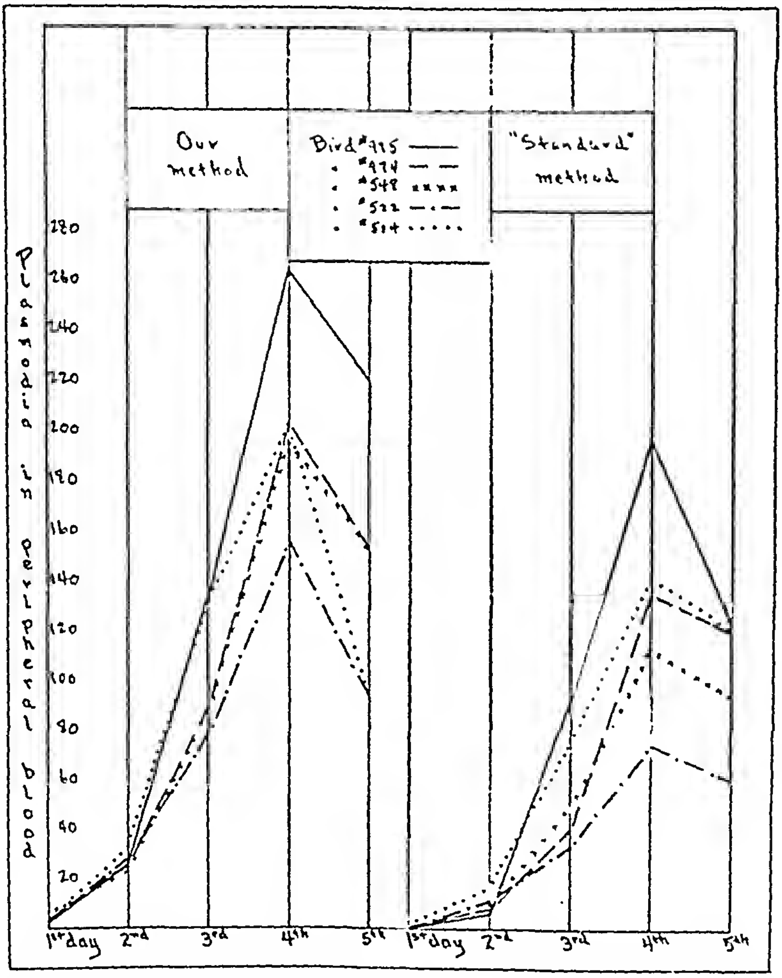

Chart 1.—Course of the *P. cathemerium* 3H2 infections in five canaries during the first five days as counted by the "standard" method and by our new method.

the average being four minutes and thirty-seven seconds. In the "standard" method 1,000 erythrocytes are examined; in our method more than twice this number are examined on all days after the first day; the extremes are 2,124 and 2,351, the average being 2,252. On the first day in our method we examine an average of 2,810 cells, or nearly three times as many as are examined in the "standard" method.

Chart I presents the counts in graphic form, the number of organisms being plotted as ordinates and the days of the infection as abscissae. The resemblance of the curves obtained by the two methods of counting seems to us in the main rather striking.

DISCUSSION OF OUR METHOD

We like our method for the following reasons: (1) No separate counts of erythrocytes and plasmodia are necessary; one merely gives the slide a hurried preliminary examination to select a suitable portion for study (a maneuver which precedes the use of all methods) and then begins examining erythrocytes and, almost incidentally, counting the plasmodia encountered. (2) There is astonishing uniformity in the number of erythrocytes examined, as shown in Table I, for the number of fields seen during the three minutes depends entirely upon the amount of time which must be devoted to the respective fields, more time being required of course to look separately at each erythrocyte in a crowded than in a scattered field. One quickly learns to omit fields in which only a few erythrocytes are present for this would obviously lead to error since the eye spends too much time in traversing unoccupied spaces, but this is easily accomplished by clicking off the stop watch and then clicking it on again when a more satisfactory area has been found. Then, too, no assumption of uniformity need be made with our method, since within reasonable limits satisfactory counts can be made, though the erythrocyte population of various fields differs quite widely. Each erythrocyte is looked at for the same length of time; that is the essence of the method. (3) By examining erythrocytes a full three minutes before declaring a smear negative we are reasonably sure it is really negative, for we have found upon innumerable occasions that a second study of three minutes and even a third practically never turns up a plasmodium. Furthermore, this three-minute study often enables us to find a plasmodium which would have been missed had we merely searched 1,000 erythrocytes; there is one such instance in Bird 548, as shown in Table I and Chart I. In our *P. cathemerium 3H2* infections the number of organisms increases sixfold to sevenfold in average instances between the first and second days; the necessity for detecting organisms on the very first day is therefore imperative if one wishes to begin treatment at the earliest possible moment.

As with all methods this has some disadvantages, but the only serious one of which we are as yet aware is that it can be employed only if one uses a stop watch having a mechanism to exclude periods of interruption and record only the actual time spent in examining erythrocytes rather than the total elapsed time. Nearly every laboratory, however, possesses one or more such watches. Of course a period of training is required to make one adept in the use of the method, but this is true of all precise procedures. We have found that for two workers to be able to check each other's counts requires only that they work together for a little while to adjust the amount of time actually spent in looking at each erythrocyte and also the speed of shifting from field to field.

SUMMARY

We have described a new method of counting plasmodia in avian malaria infections. Neither arbitrary numbers of erythrocytes nor plasmodia are

counted, but instead the slide is examined for an arbitrary period of three minutes, during which each erythrocyte is looked at individually and the plasmodial count is made rather incidentally to this examination of the erythrocytes. Despite the fact that one studies fields which vary considerably in density in using this method, the total number of erythrocytes examined varies only slightly from slide to slide. This method requires less time for its employment than the "standard" method, but enables one to examine more than twice as many erythrocytes. We believe the new method also permits earlier detection of patency than does the "standard" method.

STREPTOCOCCAL HEMOLYSIS IN VARIOUS BLOOD MEDIA*

EUGENE F. TRAUT, M.D., AND MARY S. JOHNSON, B.S., CHICAGO, ILL.

CULTURES are commonly classified as hemolytic or nonhemolytic on the basis of their appearance as surface colonies on blood agar plates or slants. This classification becomes of considerable importance in view of the selective action of sulfanilamide preparations in therapy.

Most investigators have demanded of hemolytic strains of streptococci not only the production of hemolysis on an unspecified kind of blood plate but also more exacting criteria, usually the hemolysis of definite suspensions of red blood cells of specified origin. Other workers have encountered strains whose hemolyzing character depended upon the kind of blood used. This variability in hemolysis is often a source of confusion in the exchange of cultures between laboratories using blood from different sources. On moving our laboratory from the John McCormick Institute for Infectious Diseases, where sheep's blood had been used, to Rush Medical College where we used human blood, we noted that some stock cultures consistently nonhemolytic had become hemolytic. We investigated the constancy of this important change in cultural characteristics. We also applied to our strains the tests for hemolysis advocated by Brown.[1]

Cummings[2] favors inoculating suspensions of red cells to determine hemolysis. He regards as hemolytic only those streptococci that uniformly lake human, guinea pig, and mouse blood. Those strains producing hemolysis of only certain bloods he calls pseudohemolytic. Neither hemolytic nor "pseudohemolytic" strains change chocolate agar. He found "pseudohemolytic" streptococci regularly less virulent than the hemolytic.

---

*From the Laboratories of the Presbyterian Hospital and Rush Medical College.
Received for publication, March 10, 1943.

According to Brown[1] the green-producing streptococci and pneumococci produced less hemolysis in human blood agar than in horse or rabbit blood agar. The amount of hemolysis produced by B streptococci was insignificantly less on human than on horse or rabbit blood agar. Brown recognizes hemolysis only if produced within poured agar plates or in suspensions of red cells.

To hemolyze is usually regarded as a constant, unvarying characteristic. Strains have rarely been reported as losing or acquiring this property when identical conditions are reproduced.

Brown, Irons, and Nadler[3] noted a decrease in hemolyzing ability after repeated subculture. Dana and Murray[4] describe two strains of streptococcus pyogenes as hemolyzing horse blood but as producing green and not causing hemolysis in human blood. They found another strain producing green surrounded by a hemolytic zone in sheep and rabbit blood but typically hemolyzing all other bloods. They conclude that "since there are so few variations and since these may be due to some outside influence such as immune bodies in the blood, it would seem safe to assume that the hemolytic property of streptococci is fixed and constant."

Callow[5] says "the fact that a number of strains of nonhemolytic streptococci from the blood of rheumatic and nonrheumatic patients become hemolytic after prolonged cultivation may indicate that the hemolytic function can be suppressed."

METHODS

All blood plates were made by mixing 10 c.c. of fresh defibrinated blood with 100 c.c. of agar that had been melted and cooled to the proper temperature. The plates were incubated for 24 hours before being inoculated. Cultures were streaked out until individual colonies could be identified. These colonies were studied microscopically and macroscopically after 24 and 48 hours of incubation at 37.5° C. They were then re-examined after 24 and 48 hours' refrigeration. Five-tenths c.c. of broth culture of the same strains grown 24 hours in peptone ascitic broth was added to 1 c.c. of a 5 per cent suspension of washed sheep erythrocytes in normal saline. At the same time, a similar suspension of human cells was inoculated with these same strains. The supernatant fluid of these suspension cultures was examined for hemolysis after one hour in the refrigerator. The inoculations of a given strain on human and sheep blood were made on the same day, and the effects of colony growth were noted at identical times. Other observers concurred in our observations of the bacterial growths.

Because dextrose may inhibit hemolysis, it was not used in any of our media.

Of the 17 strains of streptococci studied, 12 were isolated from the rectum according to a previously described method.[6] Two were found in throats, one in the urine, one in the blood, and one was grown from the skin in erysipelas. Two strains of hemolyzing colon bacilli were obtained from the rectums of two patients. One strain of hemolyzing colon bacilli was obtained from a specimen of urine.

RESULTS

One strain of streptococci (Bo) consistently hemolyzed human blood while producing no hemolysis in sheep blood. This strain produced green on sheep blood on one subculture, and 2 months later was indifferent on the same medium. It never produced green on human blood. Two strains of streptococci (Oss, Endo) hemolyzed sheep blood but not human blood. Six strains of streptococci (Gen, Wym, Hal, Mil, Mon, erysipelas) hemolyzed cultures of both bloods but hemolyzed sheep blood more. One strain (Wym²) produced more hemolysis in human blood than in sheep blood. Nine strains, including the culture from scarlet fever and the 3 strains of hemolyzing colon bacilli, hemolyzed human and sheep blood typically and to the same extent.

SUMMARY

The ability or inability of several strains of streptococci to hemolyze depended partly or wholly upon the origin of the blood used to enrich the culture medium. Hemolyzing ability or lack of it remained constant at least four months for a given type of blood used in culturing. Besides an absolute difference between colonies hemolyzing one kind of blood and failing to hemolyze another, there were clear-cut quantitative differences between amounts of hemolysis produced in the two kinds of blood. The variety of blood that was to make up a medium to test hemolysis might be either sheep or human but was always the same for a given strain. Taken individually, there was a great regularity in the reaction of these strains as regards hemolysis in a given kind of blood. In the group of bacteria tested, human blood was as often hemolyzed as sheep's blood.

The hemolyzing or nonhemolyzing character of a given strain remained constant for a given type of blood regardless of the method used to test hemolysis.

OBSERVATIONS BASED ON A LARGE SERIES OF COMPLEMENT TITRATIONS

MELVIN E. KOONS, M.Sc., M.P.H.*
GRAND FORKS, N. D.

DURING the past four or five years the successful application of the Kolmer complement fixation test in routine testing of blood specimens has been due, we believe, to the use of high titer complement. In recent conversations with various serologists who represented many laboratories, however, the author was much surprised to hear the many complaints regarding complement titration.

In the Public Health Laboratories of the North Dakota State Department of Health little trouble has been experienced with complement per se, when used in the Kolmer complement fixation test. In view of the difficulties exercised in the complement titration, it was deemed worthwhile to point out the experience in North Dakota. Two points bear out the above statement: (1) the consistently low titer of complement as used in other serologic laboratories, and (2) the available records of high titer complement as used in the North Dakota Public Health Laboratories.

From experience most serologists will agree that for the efficient performance of complement fixation tests, good complement is a decided asset. The use of poor complement invariably gives a "sloppy" run, accompanied by slow clearing of the test tubes with the end result of a large number of doubtful readings which are eventually proved to be negative.

Many authors have pointed out the importance of diet upon the quality of complement; however, no attempt will be made here to cite any specific literature. A complete picture of the entire system used in North Dakota should suffice, and it is hoped some benefit may be derived therefrom.

CARE OF GUINEA PIGS

The guinea pigs used as a source of complement are full-grown male or nonpregnant female animals purchased on the open market. No particular breed is especially purchased. The pigs are purchased when small and grown to maturity in our laboratories. The animals are quartered inside the year around, with the temperature of the room varying from 60° to 80° F., depending upon outside conditions. They are kept in metal cages of a size two by four feet, averaging from 10 to 12 per cage. Males and females are kept separately. The cages are cleaned once a day and animals are fed each morning.

The diet consists chiefly of Purina Rabbit Chow Checkers (entire ration) manufactured by the Ralston Purina Company, St. Louis, Mo. The ingredients are ground oats, corn meal, wheat germ, soy bean oil meal, corn germ meal,

*Director, Division of Laboratories, North Dakota State Department of Health.
Received for publication, March 22, 1943.

alfalfa meal, wheat middlings (gray), molasses, riboflavin supplement, 1.5 per cent calcium carbonate (limestone), 0.5 per cent iodized salt. A portion of these checkers is kept in front of the animals at all times. During the winter the pigs are fed freshly cut carrots at least once a day and during the summer freshly cut grass is substituted for the carrots. Hay is placed in the cages twice a week and year around. Fresh water is put in each cage every morning and twice a day in extremely hot weather. With this diet our experience has been that the pigs gain weight steadily and always look "well."

BLEEDING OF ANIMALS

All feed is removed from guinea pigs at least eighteen hours before they are bled, although water is allowed in the cages. Usually from 6 to 10 pigs are bled at each period. Approximately 8 c.c. of blood is collected from each animal. The pigs are bled about once every six weeks.

The animals are lightly anesthetized with ether and bled from the heart with a 20 gauge needle and a 10 c.c. syringe. The blood from each animal is placed in a separate test tube and allowed to remain at room temperature for approximately one hour. The tubes are then placed in the refrigerator overnight.

The following morning the serum is poured from the clots and centrifuged for ten minutes at approximately 1,500 revolutions per minute. The complement is pooled and placed in tubes containing about six c.c., then placed in the freezing compartment of an electric refrigerator at a temperature of approximately −8° C.

TITRATION OF COMPLEMENT

Complement prepared as above gives a high usable titer for approximately three weeks. The hemolysin used is of a high titer (generally 1:8,000) and is purchased from a commercial house. The antigen used is purchased directly from Dr. John A. Kolmer in Philadelphia.

The amount of complement needed for the day's run is thawed by placing tube in a small amount of cold water about thirty minutes before titration is to be set up. A 1:30 dilution of complement is used in the titration. All saline used in the titration is kept in the refrigerator in a large flask; hence cold saline is used throughout.

In a series of ten test tubes the complement titration is set up as shown in Protocol I.

It will be noted that after the complement antigen and saline are added the tubes are placed in water bath at 37° C. for only thirty minutes; after the addition of hemolysin and corpuscles, the titration is read when the tubes have been in the 37° C. water bath for only twenty minutes. As in all complement titrations, the smallest amount of complement just giving complete sparkling hemolysis is the exact unit. The next higher tube is the full unit which contains 0.05 c.c. more complement.

Table I shows the results obtained on 612 complement titrations by closely adhering to the above procedure.

Examination of Table I indicates clearly that most of the complement titrations show a titer of 0.25 c.c. or over. Of the 612 titrations, 84.8 per cent

gave a titer which could be used in the complement fixation test of 1:50 or above. This means that only 15.2 per cent of all complement titrations gave such titer that complement was used below 1:50. Further study shows that 11.0 per cent of those below 1:50 were usable at a dilution of 1:43. That the titers obtained were high is indicated by the fact that in 14.4 per cent of the titrations, complement was used at a dilution of 1:75 or higher. The largest number of titrations (70.4 per cent) showed that complement could be used at a dilution of 1:50 and 1:60.

*Frozen guinea pig serum used in all titrations (1 day to 3 weeks old).

The complement giving a titer of 0.15 c.c. and 0.1 c.c. were those titrated generally within three days after being obtained from guinea pigs. The opposite was found to be true, in that those titers on the lower end of the scale were generally encountered when complement was from 17 to 21 days old.

CONCLUSIONS

1. The successful application of the Kolmer complement fixation for syphilis in North Dakota has been due to a large extent to the use of high titer complement.

2. The care of guinea pigs, especially diet, is essential to the production of high titer complement.

3. Complement kept in a frozen state has proved to be highly satisfactory when not over three weeks old.

4. Scrupulous care as to technique will result in good complement titrations.

THE DERMOFLUOROMETER*

An Instrument for Objective Measurement of the Fluorescence of the Skin and Organs and the Objective Determination of Circulation Time and Capillary Permeability

Kurt Lange, M.D., and S. E. Krewer, New York, N. Y.

SOME time ago Lange and Boyd[1] showed that fluorescein, injected intravenously as a 5 per cent solution and irradiated by long wave ultraviolet can be seen in the capillaries of the skin and mucous membranes. This permits the determination of circulation time to different parts of the body and the establishment of adequacy of blood supply to these structures.[2, 3] Fluorescein can be watched traveling with the blood stream, permeating the capillary wall, and staining the tissue cells.

This method can be used routinely as a simple procedure to locate exactly the site of a vascular occlusion[2] or to ascertain how much blood flow to an organ or section of skin is diminished by the difference in depth of staining per unit of time. Extensive studies made it obvious that an awareness of an area of diminished blood supply was extremely valuable; quantitative measurement of the amount of fluorescein present at a given moment in any district of the skin or mucous membrane added considerable objective information.

Fluorescence of this dye is excited by blue and violet visible light as well as by an ultraviolet light source. This makes it possible to employ an incandescent lamp provided certain precautions are taken. While the ultraviolet light source equipped with adequate filters is unsurpassed for demonstration and visualization of vascular lesions, incandescent blue light is very convenient for actual measurements since it is smaller and produces less heat.

When we adopted the incandescent lamp for exciting fluorescence, it became feasible to design a compact unit which combines the light source as well as the phototube in rigid relative positions to each other (Fig. 1). The exciting (primary) blue light impinges upon the body while the yellow-green fluorescent (secondary) light (i.e., light of longer wave length than the primary light), of the blood stream, evoked by the blue light, is registered by the phototube; it is necessary to prevent the primary light from reaching the phototube by reflection from the skin or organ surface. This is accomplished by a filter F_1 (Fig. 2), in the primary light beam and filter F_2 set in front of the phototube. Filter F_1 transmits blue light only and absorbs practically all light of a wave length *longer* than 5000 Angstrom units. Conversely, filter F_2

*From the Department of Medicine, New York Medical College, Flower and Fifth Avenue Hospitals and Metropolitan Hospital-Service (Research Unit).

Aided by a grant from the John and Mary R. Markle Foundation.

Received for publication, April 8, 1943.

absorbs all light of a wave length *shorter* than 5000 Angstrom units and transmits mainly yellow-green light characteristic of the fluorescence of fluorescein. Since all these filters have a small undesirable leakage in the infrared, the phototube selected for this work is entirely insensitive to infrared radiation.

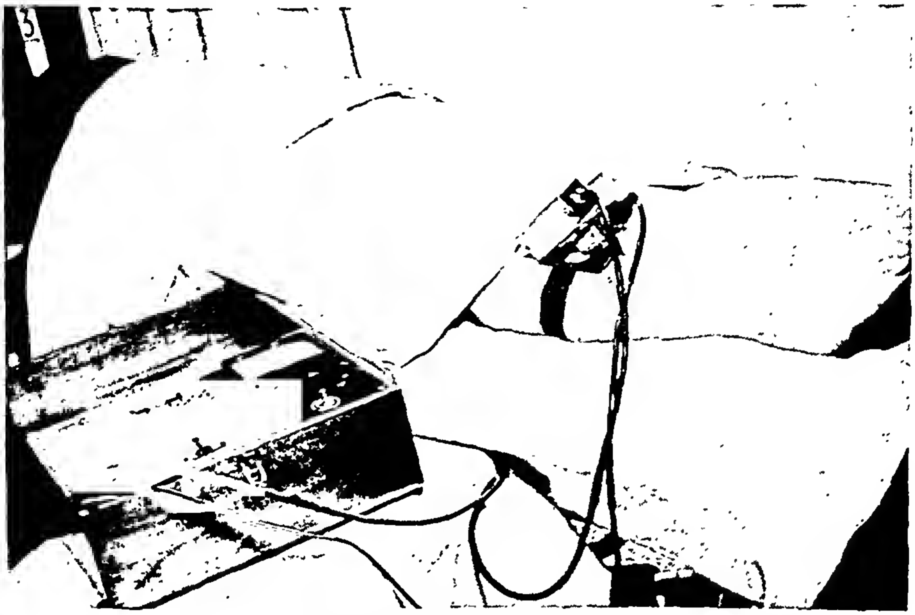

Fig. 1.—The dermofluorometer. The search unit comprising the light source and the phototube is attached to the leg of a patient.

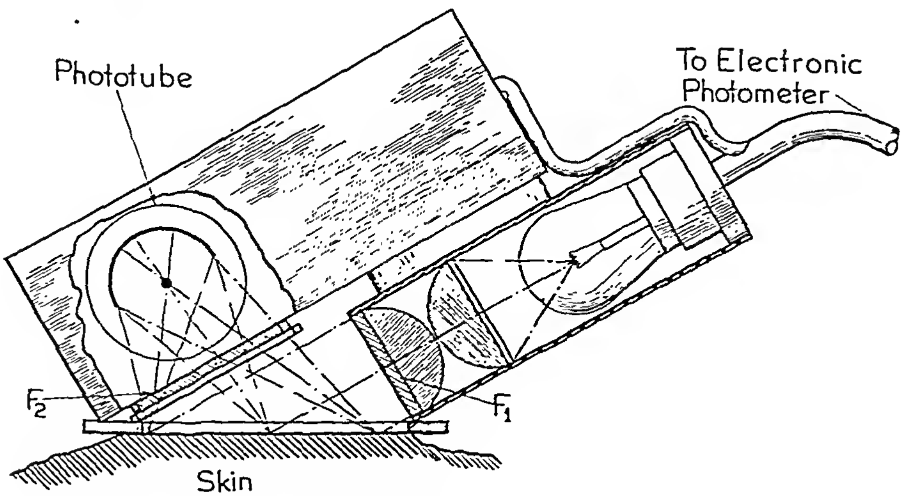

Fig. 2.—Schematic drawing of the search unit. F_1 blue filter in front of light source. F_2 yellow filter in front of phototube.

Because of these provisions, the light registered by the phototube before injection is negligible and is taken care of by a "background reading," which gives the actual degree of deflection of the instrument before the injection of fluorescein. The deflection following the injection of fluorescein therefore rep-

resents the effect of this injection quantitatively. The current output of the phototube is amplified approximately 3×10^5 in the electronic photometer.*

Table I shows the deflections of the instrument when standard solutions of fluorescein are tested; it proves that the device deflects proportionately to the concentration of fluorescein employed.

TABLE I

DILUTION OF FLUORESCEIN	DEFLECTION OF INSTRUMENT
1: 500,000	43.0
1: 1,000,000	22.0
1: 5,000,000	4.5
1:10,000,000	2.4

The instrument is used as follows: In a darkened room, several test spots of the body to be examined are touched with the instrument and the "background" deflection is noted. The instrument is then attached with a usual rubber strap to the spot at which the circulation time is to be observed. Ten cubic centimeters of a 5 per cent fluorescein solution are injected intravenously, and the time elapsing between the beginning of the injection and the initial deflection of the instrument is measured with a stop watch. This constitutes the circulation time to this area. A mouthpiece made from lucite, a translucent material, can be used to determine the circulation to the lips or gums if this is preferred to visual observation. Subsequently, all test spots are touched with the instrument, and the deflections of the photometer are read. From the results thus obtained, "background" readings are subtracted in order to obtain absolute fluorescein values. Thus a curve is obtained for each area of the body surface which indicates how much blood and, with it, fluorescein is reaching this district per time unit.

To prove that these deflections are really dependent upon blood supply, a blood pressure cuff was put around one thigh of a patient and inflated to a pressure between systolic and diastolic level. Subsequently comparative readings were taken on the normal and on the compressed leg of the patient, and the values were noted. Such a test is shown in Fig. 3. It indicates clearly that the values in the leg with partial occlusion are considerably lower than those in the normal leg.

To standardize the values found with different instruments, the following basis was adopted: one skin unit is the deflection caused by an alkaline fluorescein solution of 1:30,000,000 in a cuvette of 5 millimeters depth, the glass of which shows no absorption for the exciting light.

The first part of the curve thus obtained depends primarily upon the amount of blood reaching a given area per unit of time and upon capillary permeability. It will be shown in another paper that changes in plasma proteins within physiologic limits do not influence the amount of fluorescein available for diffusion into the tissue fluids. The last part of the curve is strongly influenced by the excretory function of the kidney.

Fig. 4 shows a typical normal curve recorded at the leg, and the curve of a patient with arteriosclerosis of the extremities, and one from a patient suf-

*The complete instrument was manufactured for us according to our specifications by the Photovolt Corporation, New York, N. Y.

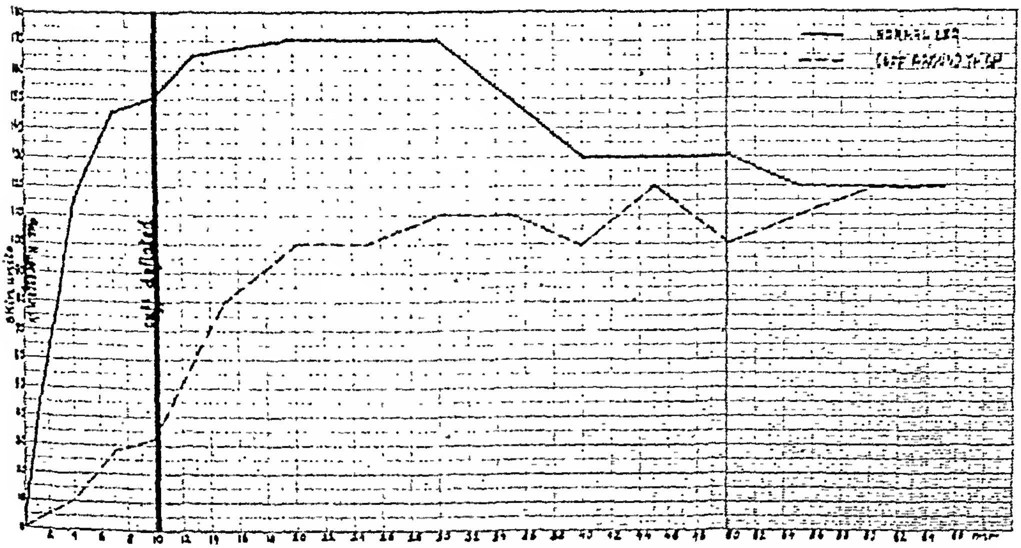

Fig. 3.—Dermofluorometer readings in a patient who had a blood pressure cuff inflated to a pressure between systolic and diastolic blood pressure around one thigh. 10 c.c. fluorescein were injected intravenously. Ten minutes after injection the pressure in the cuff was released.

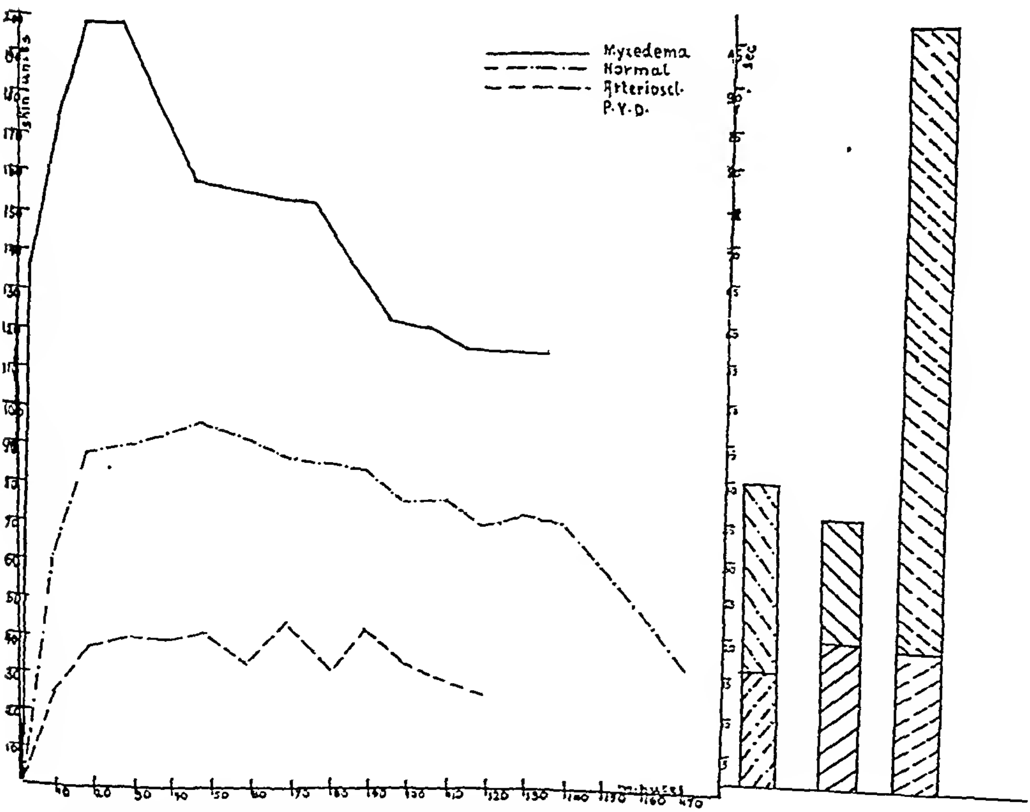

Fig. 4.—Dermofluorometer curves of three patients, one of whom is suffering from generalized arteriosclerosis, one from myxedema, and one, a normal person. The blocks give the circulation time in seconds from the arm to the lips and to the right leg respectively for each case.

fering from myxedema. In myxedema, the capillary permeability is especially high, and this may be the explanation for the peculiar skin condition and the tendency to form transudates, especially in the pericardium. By applying the instrument to different parts of the extremity of an individual with peripheral vascular disease, very often the exact place at which the artery narrows decidedly can be foretold. At the corresponding skin level, skin fluorescence suddenly decreases. At the same time the circulation time to a limb with a generalized arteriosclerosis is usually markedly prolonged. In a normal person the arm to leg circulation time should not exceed twice the arm to lip time. Formerly this could be seen with long wave ultraviolet, but now it can be measured exactly with the dermofluorometer.

SUMMARY

The instrument described permits quantitative measurements of the fluorescence values obtained when patients with vascular disorders are tested with fluorescein. A skin unit of fluorescein is defined. The exact location of a vascular stenosis can be determined with this device. Capillary permeability can also be determined.

RAPID DIAGNOSIS OF MALARIA BY THE USE OF A WRATTEN LIGHT FILTER

RUBEN CARES, MAJOR, M.C., CAMP COOKE, CALIF.

CONTRAST filters are necessary in photography of colored or stained objects but can also be utilized in clinical microscopy. The visual contrast afforded can shorten the period of search required in a number of microscopic examinations before a negative report is issued.

A diagnosis of malaria after a short search for the parasite is not the rule. Many oil immersion fields must be examined before one intracellular organism is seen. When the young malarial forms, the "signet-ring" merozoites, are present, the closest study is required. In an early case or in a recurrence, the relative infrequency of infested red cells may cause the issuance of a false negative report. The paleness of the blue cytoplasm, often thinned out to little more than a line, allows an understandable oversight in running through hundreds of red cells. This is particularly true if no mature and larger forms are encountered, a not unusual condition.

Received for publication, April 15, 1943.

The thick drop method of crowding the red cells into the oil immersion field does not often disclose the intracellular location of the parasite. It is difficult to increase the staining intensity of the malarial organism by the routine hematologic stains.

A suitable light filter will produce the maximum contrast between the parasite and the red cells without of course affecting the stain for routine study. Blood stains are essentially a combination of methylene blue and eosin. It was found that of the various Wratten light filters* the E light red filter (series 23A) has a spectral transmission range parallel to that of eosin.[1] Moreover, this filter transmits a higher percentage of incident light in the red part of the spectrum than does eosin. Consequently the red cells actually appear lighter. The absorption of all blue (and green) light by the E filter renders the blue-stained elements distinctly darker. This contrasts sharply with the pale shadow or "ghost" rendition of the red cells. In a specified examination period 3 to 4 times as many parasites can be located as with normal lighting.

The simplest and least expensive form of the E filter is the dye-stained gelatin film supplied in one- or two-inch squares obtainable at photographic supply stores. A two-inch square can be cut up into a number of filters between cardboard mounts. These can easily be fitted to cover either the substage condenser or the ocular, and likewise can be instantly removed to study the located parasite by straight lighting.

Where analagous problems in microscopic studies exist, the enhanced contrast of light filters may similarly be utilized.

MACROSCOPIC BLOOD TYPING*

A Modification of the Method of Thalhimer and Myron

S. W. Sappington, M.D., Philadelphia, Pa.

THE macroscopic method of blood typing, when compared with the standard microscopic method, offers advantages of economy in time and equipment and ease of performance and reading. It makes typing afield, such as outside of hospitals and under war conditions, simple and practical. If it can be shown to equal or exceed the microscopic method in accuracy, it would seem to be the method of choice. A gross method of typing has been described by Thalhimer and Myron[1] for use with the globulin fractions of pooled sera, the idea apparently being that the serum concentration thus attained would furnish agglutinating titers adequate for such a test. The method consists essentially in putting a large drop of A and B serum concentrate side by side on a card; placing a small drop of the undiluted blood to be tested at the side of each drop of serum; mixing the two drops with the adjacent blood; and, after a minute's rotation, observing the presence or absence of agglutination.

We used these concentrated sera and the method with the same satisfactory results indicated by Thalhimer and Myron, but while doing so and employing unpooled and unconcentrated sera for comparison, it was noted that single sera not infrequently gave equally good or superior agglutination. This suggested to us the possible value of an appraisal of unmodified single sera for the purpose. Accordingly, about 1,500 random sera were tested in various ways pertaining to the application of this method, controlling all results by the microscopic method. Sundry aspects of the results are submitted below.

Undiluted Versus Diluted Blood.—Undiluted blood taken directly from the finger necessitates an immediate performance and reading of the test but, on the other hand, requires little equipment and time and may be more desirable at the bedside and outside of hospitals. Blood diluted with an anticoagulant may be tested at one's convenience as to time and place and permits repetition of the test when desired. Our preference for diluted blood is based on the results of typing over 200 donors with both undiluted and diluted blood macroscopically and diluted blood microscopically. Here it was found that typing with undiluted blood was more open to error in reading results than with diluted blood, as the greater concentration in the former does not permit as clear a view of the developing agglutination. Likewise, it was noted that typing with anemic undiluted blood gave a clearer picture than normal concentrated blood for the same reason.

A blood dilution which gave a more readable agglutination than the use of pure blood and yet was not so diluted as to weaken the picture was one part

*From the Clinical Laboratories, Hahnemann Hospital. Technical assistance was given by K. E. Simmons and M. C. Krause.

Received for publication, April 22, 1943.

of blood to two parts of diluent. This dilution, while very satisfactory for macroscopic tests, is too low for microscopic work, which requires quite dilute suspensions.

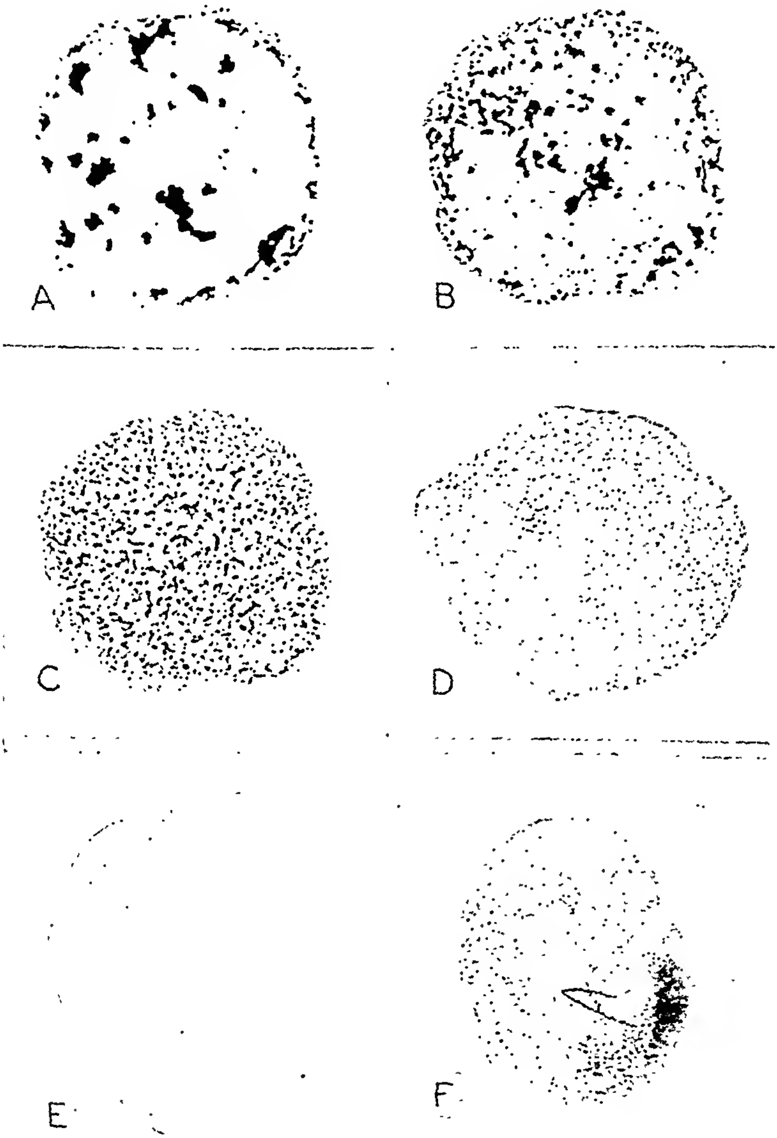

Fig. 1.—*A*, *B*, *C*, and *D* photographs show various degrees of macroscopic agglutination of red calls; *E* illustrates absence of agglutination; *F* photograph shows false clumping as seen occasionally in dried mounts.

The Blood Diluent.—Sachs,[2] in a study of the role of salt concentration in blood grouping tests, found that hemagglutination with unheated and heated serum was hastened and intensified in a high salt concentration, and he recommended that the cells for blood grouping be suspended in a 2 or 3 per cent sodium chloride solution. He stated that suspending the corpuscles in this stronger sodium chloride solution is a safe way of avoiding false negative reac-

tions such as may occur on cross matching. He also found that although the speed and strength of agglutinations are at first much increased with high salt concentration, the end titer may be lower.

On this basis, gross blood typing tests were done with a suspension of one part of blood in two parts of a 1 per cent solution of sodium citrate in 2 per cent sodium chloride. Comparison of the results with this solution with those attained with a 0.9 per cent saline solution confirmed the claims of Sachs. It was found that gross agglutination appeared uniformly more promptly in the 2 per cent salt suspension and that the advantage, while not great, was of sufficient value to warrant the use of the stronger solution.

Evaluation of Sera for Typing.—As a first preliminary test, an effort was made to type 100 unselected samples of blood serum by the gross method, and this was successful in all but 2 sera in which the titer was too low to give conclusive clumping. In a second preliminary test, an attempt was made to type 100 red cell suspensions using as typing sera A and B samples of the random sera of the first experiment. In doing this, sera of average or less than average agglutinating strength were purposely employed instead of the stronger sera. The entire 100 blood suspensions were thus typed correctly.

Having shown that blood may be readily typed by the macroscopic method using either known sera or known red cell suspensions, the problem was studied more exactly in a series of tests of donors' sera by noting carefully the time of gross agglutination and the size and character of the clumps and comparing these with the agglutinating titer of the respective serum. There were thus tested and titrated 100 A and 100 B sera. It was found that the isohemagglutinin titer and the agglutinative ability as measured macroscopically did not always agree quantitatively, and that in occasional individual cases, there was a marked discrepancy,* an experience similar to that of Thalhimer and Myron.[1] On the whole, however, as these authors point out in their work, there was a general trend toward correlation. A serum with a titer above 1/80 was usually adequate for gross typing. But for the purposes of the test, it was found better to rely on the gross results as seen in the rapidity and readability of the reaction than the titer. The rapid production of coarse clumps is the macroscopic evidence of maximum agglutination. Sera producing beginning agglutination in ten seconds or less and complete agglutination within

*In the titration tests, five dilutions of serum in normal saline were made as follows: 1:20, 1:40, 1:80, 1:160 and 1:320. To 1 c.c. quantities of such dilutions in small test tubes was added 1 drop of a 1:3 fresh suspensi[illegible]. This mixture was allowed to stand an hour at room temperature, [illegible] and then placed in the refrigerator overnight to be given a final re[illegible] first list below illustrates average comparative readings of titer and macroscopic clumping. The second illustrates selected examples of discrepancies in such readings: it is only fair to say that these are rare.

TYPE	TITER	GROSS CLUMPING	TYPE	TITER	GROSS CLUMPING
A	1:40	++	A	1:40	++++
A	1:320	++++	B	1:40	+++
A	1:80	++	B	1:160	++
A	1:160	+++	A	1:20	++
A	1:40	+	B	1:80	++
A	1:20	+			
B	1:80	+++			
B	1:40	++			
B	1:320	++++			
B	1:20	++			

one minute were graded ++++. Sera producing beginning agglutination in ten to fifteen seconds and complete agglutination in sixty to seventy seconds were graded +++. It is important to note that complete clumping may be present within these limits in the form of fine or medium-sized masses, though larger clumps may form later on standing. Sera grading 3 or 4 plus were serviceable for macroscopic typing. Thus measured, about 20 per cent of the A sera and 40 per cent of the B sera met these standards, so that one may anticipate that 1 out of 5 A sera and 2 out of 5 B sera will be adequate for macroscopic tests. It is especially important to use strong B sera on account of the subgroups of A bloods, and this is not difficult as strong B sera are quite common.

In the same way, fifty O sera were grossly tested and titrated against suspensions of A and B cells. Again it was found that the macroscopic clumping reaction afforded better indications of the agglutinative ability of the serum than titration. Usually O sera are stronger in anti-A agglutinins than anti-B agglutinins. In 50 sera, the anti-A were stronger than the anti-B agglutinins in 34 instances; in 15 instances, the anti-A and anti-B agglutinins were approximately equal in strength; and in one case, anti-B agglutinin was stronger. Of fifty O sera, 34 gave a 3 or 4 plus clumping reaction against A cells, and 12 gave a 3 plus clumping against B cells. As measured by macroscopic clumping, about 2 out of ten O sera may be expected to give a 3 plus or greater agglutination with both A and B suspensions. Such sera are adequate for control tests.

Cross typing of blood as a preliminary to blood transfusion involves the use of sera of unknown and perhaps low agglutinin values whether the tests are done by the macroscopic or microscopic method. In a series of 100 routine cross typings of donor and donee, in which both methods were applied, the gross method agreed with the microscopic test throughout. In our routine cross typing, however, we still employ both the gross and microscopic methods, as we wish by continued observation to be sure of the accuracy of the gross tests before dropping the standard microscopic one. Our further experience suggests this will be possible.

Reading of Results.—If the blood typing is done in the usual way, i.e., using A and B ++++ or +++ type sera against the donor's or recipient's red cell suspensions, the gross clumping is so prompt and self-evident in the great majority of instances that the type may be read macroscopically within a minute (Fig. 1 *A, B, C, D,* and *E*). If, on the other hand, an unknown serum is to be typed with A and B red cell suspensions, the rapidity and degree of agglutination are dependent on the unknown agglutinin titer, and may, in a serum poor in agglutinins, exhibit slow action and poor clumping, though it is nearly always possible to be certain of the type. Such results are quite exceptional, and doubtful cases, when controlled by typing through the blood suspensions, usually prove to be the type originally suspected.

With the usual large- and medium-sized clumps, the reading is perfectly simple. Infrequently, when the clumps are fine and formation slow, the reading is delayed and sometimes difficult. Here and in other instances, the additional use of a high titer O serum may be helpful. For example, if there is no

clumping with A or B serum and definite clumping with O serum, the results are erroneous. Again, when there is doubtful or unsatisfactory agglutination with A or B serum, the absence of clumping with O serum makes it fairly certain the type is O. If, after the use of O, A, and B sera, there is still doubt, the test should be reversed by trying the gross agglutinative effects of the serum of the blood to be tested against known emulsions of A and B cells. Under such circumstances, it should be kept in mind that if the serum to be typed is an O, it will usually clump A cells very promptly before there is any visible clumping in the B cells. It is therefore essential not to cease rotation of the card when A clumping appears, thus mistaking it for B serum, but to prolong it to be sure that the B cells also will not clump.

Final readings for type should be done while the mount is freshly wet. Card paper of the thickness recommended warps quickly under the influence of the blood-serum mixture, and correct reading is more difficult if the test is put aside to be read later. We do not feel it is worth while to preserve the dried individual tests as part of the clinical record, as the appearance changes somewhat in the dried specimen and in certain cases may give a false impression of type. In drying or dried blood-serum mixtures, a fine granulation may develop and be mistaken for true clumping by the inexperienced. (Fig. 1 *F*.) Negative bloods, that is, those like type O which show no clumping with A or B serum, are of necessity rotated longer in watching for possible agglutination; but this should not be continued too long, for example, four or five minutes, as a fine false clumping may be apparent.

One should not get the impression from the foregoing details, which are given largely as precautionary information, that macroscopic typing is a matter of hazards and difficulties. On the contrary, we found macroscopic typing quite as reliable as and more easily performed than the microscopic method. In the case of a type O patient showing weak irregular isoagglutinins which clumped not only her own cells but all other O types, the aberration was picked up quite as well by the gross as the microscopic method. And in the case of a sailor, typed by the Navy and wearing an O tag, the macroscopic method detected the error and showed he was an A type.

EQUIPMENT

A, B, and O ++++ or +++ typing sera in drop bottles. Keep, in intervals, in refrigerator.

White card index paper or No. 2 Bristol board cut in strips 10 × 4 cm.

Blood diluent, 1 per cent sodium citrate in 2 per cent sodium chloride.

Capillary pipettes and nipples. Small test tubes (7.5 × 1.3 cm.). Toothpicks.

Typing sera are easily obtained by taking an extra test tube of blood when bleeding donors. When ten or more of these sera are on hand, appraise them by the macroscopic method against A and B blood suspensions. Two or more out of ten will have a gross clumping value of +++ or ++++ and are serviceable for macroscopic tests.

METHOD

Place 8 drops of diluent, measured with a capillary pipette, in the small test tube, and add to it, collected with the same pipette, 4 drops of blood from

the patient's or donor's finger. This makes a 1 to 3 dilution which will keep; it is of the proper density and sufficient in quantity for repeated tests. Immediately or at one's convenience, place a large drop of each test serum, at least 7 mm. in diameter, on a labeled card strip, and beside it, a small drop of the diluted blood, one-fourth to one-third of the size of the serum drop. Both serum and blood drops will assume and retain an almost globular form on card paper. If two types of sera are used, the order from left to right should always be A and B; if three are used, the order should be A, B, and O. Mix each diluted blood and the respective serum with the flat end of a separate toothpick, spreading the mixture to a circle about 3 cm. in diameter. Avoid small circles. At once rock the card in various directions for a minute; let stand for twenty to thirty seconds; rerock the card for ten to twenty seconds. Read results while freshly wet. In rare instances, when clumping is slow or indistinct in one or both mixtures, further rotation may be necessary, but this should not be protracted beyond two or three minutes, as a fine false clumping may lead to incorrect readings. Dried mixtures not infrequently show this fine false granulation.

SUMMARY

In a study of the macroscopic method of blood typing described by Thalhimer and Myron, the following modifications are recommended: the use of diluted blood; a diluent of high salt concentration; the use of single, unconcentrated typing sera of high gross agglutinative ability. The reasons for these changes are discussed.

In our experience with about 1,500 controlled tests, the macroscopic blood method of blood typing here described equaled the microscopic method in accuracy and was superior to it in rapidity, simplicity, and economy. It has now been used as the routine method in our laboratories for four months with equally satisfactory results.

AN INHIBITION PHENOMENON IN PRECIPITATION TESTS FOR THE SERODIAGNOSIS OF SYPHILIS*

RACHEL BROWN, PH.D., ALBANY, N. Y.

THE purpose of this communication is to point out an inhibition phenomenon that may be a source of error in the precipitation test for the serodiagnosis of syphilis. The colloidal state of some sera is such that, although reaction between antigen and reagin apparently takes place, the formation of visible aggregates is inhibited. A serum of high activity may thus appear to be of only slight activity or to be nonreactive. The properties of the sera that give rise to this phenomenon are not understood; but the technique of precipitation tests should be such that sera of this character may be recognized and their reactivity interpreted correctly.

The inhibition phenomenon has been observed occasionally in an oversensitive procedure,[1a, 2] and there is reason to suspect that it may occur also in other tests. Although inhibition of precipitation may occur simultaneously with a prozone reaction,[3, 4] early recognized as a source of error, the two phenomena appear to be distinct and should not be confused. The properties of serum that inhibit precipitation do not disappear on dilution with physiologic saline solution. It has been found, however, that centrifugation† of the tests of such sera will cause the formation of large flaky aggregates. Similar treatment of typically negative or weakly reacting test mixtures does not cause precipitates of this character.

In Table I are presented the results of precipitation tests performed on four successive specimens of blood serum from a patient undergoing malarial therapy for syphilis of the central nervous system. The sera were tested undiluted and in a series of dilutions in physiologic saline solution with the antigen adjusted for oversensitive preliminary tests. With the first three specimens, reactions originally of insignificant degree became marked on centrifugation for five minutes at about 2500 revolutions per minute. The fourth specimen gave typical results. The attending physician knew of nothing in the patient's history to account for the change in serum properties.‡

These same specimens were examined with two other antigens for precipitating activity. When tested in a presumptive procedure,[5] the first three specimens failed to react, while the fourth specimen reacted as follows: undiluted, 2+; diluted: 1:5, 4+; 1:10, 4+; 1:20, 4+; 1:30, 4+; 1:40, 4+; 1:50, 4+; 1:60, 3+; 1:80, 2+; 1:100, +; and 1:150, –. They were also examined, for pur-

poses of comparison, with a carefully adjusted mixture of relatively pure lecithin and cardiolipin* sensitized with cholesterol. In this instance typical results were obtained by the regular procedure without centrifugation (Table I). Thus, although the colloidal condition of a serum is such as to inhibit the formation of a precipitate, this irregular behavior is also influenced by the antigen.

TABLE II

REPORTS OF PRECIPITATION TESTS WITH TWO SPECIMENS FROM THE WASHINGTON SEROLOGY CONFERENCE

		TEST			
SPECIMEN NO.	OVERSENSITIVE PROCEDURE	A	B	C	D
830	3+, +, ±, –* Positive Atypical	Positive	Negative	Doubtful	Negative
1090	±, ±, +, –** Doubtful Atypical	Negative	Positive	Positive	Positive

*The last three tubes containing 0.1 c.c. of undiluted serum and serum diluted 1:5 and 1:25 respectively with 0.02 c.c. of antigen, when centrifuged, read 4+, 4+, 3+.

**The first tube containing 0.05 c.c. of serum and 0.08 c.c. of antigen and the second and third tubes containing 0.1 c.c. of undiluted serum and of serum diluted 1:5 with 0.02 c.c. of antigen each, when centrifuged, read 4+, 4+, 4+.

These two specimens had titers greater than 10 in the quantitative complement fixation test.[1b]

Some of the discrepant results obtained in different test procedures may be due to this phenomenon. Table II records a few of the results obtained with two specimens, No. 830 and No. 1090, in the Washington Serology Conference.[2] Both specimens were from patients with diagnoses of syphilis of over four years' duration. Based on the results of the oversensitive procedure as performed routinely, the specimens were reported as "atypical positive" and "atypical

*The lecithin and cardiolipin were kindly supplied by Dr. Mary C. Pangborn.[6]

doubtful," respectively. Subsequently the tests were centrifuged, and evidence of marked reactions was obtained. The conflicting reports suggest that doubtful and negative results may be misinterpreted owing to failure to recognize the inhibition phenomenon.

The problem is one that should be considered for individual precipitation procedures; methods should be developed where necessary by which specimens that require special treatment may be detected. The recognition of the phenomenon in a given instance would require the use of more than one reaction mixture to indicate atypical findings.

CONCLUSIONS

The precipitation test for the serodiagnosis of syphilis is evidently subject to a phenomenon of inhibition in which the reaction between serum and antigen becomes manifest only under certain conditions. This inhibition appears to be distinct from the prozone phenomenon although the two may occur together. The phenomenon is of sufficient importance to require further investigation and careful consideration in the standardization of the technical procedure of precipitation to avoid the possibility of a false interpretation of the results.

CHEMICAL

MODIFICATIONS IN METHODS FOR THE PRECIPITATION AND ASSAY OF INCREASED AMOUNTS OF PITUITARY GONADOTROPIC SUBSTANCES IN THE URINE*

PATRICIA H. SMITH, M.D., FULLER ALBRIGHT, M.D., AND ELIZABETH DODGE, A.B.
BOSTON, MASS.

THE demonstration of those pituitary gonadotropic substances in the urine which are follicle-stimulating has depended upon their precipitation and subsequent assay in a chosen test animal. Zondek (1930) precipitated urine with alcohol and used the ovarian response of immature rats as the end point of assay. Hamburger, in 1933, and Albright, Halsted, and Cloney, in 1935, used the alcohol precipitation method of Zondek, but observed the ovaries of infantile mice. Thomsen and Pedersen-Bjergaard (1936) used tannic acid and studied uterine enlargement together with ovarian weights in rats, and Callow and Callow (1937) modified their tannic acid method of precipitation. Levin and Tyndale (1936) also used tannic acid and were the first to use the weight of the infantile mouse uterus as the end point of assay. Catchpole, Greulich, and Sollenberger (1938) reported a method in which tungstic acid was the precipitating agent and in which mouse uterine weights were recorded. Heller and Heller (1939) used alcohol precipitation together with ovarian and uterine weights in immature rats as the test objects. In the experience of this laboratory all of the above procedures have been tried with the exception of the method in which tungstic acid was used, and no one procedure has proved entirely satisfactory. A method has therefore been developed which gives consistent and satisfactory results: alcohol was chosen as the precipitating agent; the volume used was increased, and enlargement of the uteri of infantile mice was the criterion of a positive test. Besides its use in the study of the menopause and in the sorting out of the various types of hypogonadism in males and females, it has led to the elucidation of two clinical conditions reported by Albright, Smith, and Fraser (1942) and Kleinfelter, Reifenstein, and Albright (1942).

CHOICE OF PRECIPITATING AGENT

Both alcohol and tannic acid as precipitating agents received extensive trial in this laboratory. The former has given excellent results; the latter as here

*The expense of this study was partly defrayed by the Committee for Research in the Problems of Sex of the National Research Council.
From the Biological Laboratory of the Massachusetts General Hospital and the Department of Medicine of Harvard Medical School.
Received for publication, August 5, 1943.

employed* was not consistently satisfactory (see Table I). At the suggestion of Fevold (1939), eight volumes of alcohol instead of four were employed, and the data showing the efficacy of alcohol as compared with tannic acid are given in Table I. Since certain patients after the menopause have so much pituitary gonadotropic substances in the urine that an assay can be made by injecting such urine without precipitation into animals, yields obtained by this procedure (so-called "direct method") were compared with those obtained by precipitation with alcohol or tannic acid followed by redilution.

Study of the table reveals that positive assays were obtained more frequently with the use of alcohol than with the use of tannic acid. Thus, of the ten cases studied, six showed better yields with alcohol than with tannic acid (Cases 1, 2, 3, 4, 9, and 10); in four cases (5, 6, 7, and 8) the yields were the same: in no instance was the yield with tannic acid better. The reason for the complete failure of the tannic acid method in certain instances (e.g., Cases 1 and 3) remains obscure. Since good results were obtained in some instances, it is conceivable that there is some error in technique in the method as used.

CHOICE OF METHOD OF BIOLOGIC ASSAY

In the selection of the method of biologic assay one may choose the rat or the mouse as the test animal and the ovary or the uterus as the significant organ of response. Hamburger (1933) pointed out that the mouse ovary was a more sensitive test object for pituitary gonadotropic substances than the rat ovary. Albright, et al. (1935) confirmed this. Levin and Tyndale (1937) reported data in the use of the uterine weights in immature mice as the criterion of a positive test but used tannic acid as the precipitating agent. This laboratory has followed the procedure of Levin and Tyndale in the use of the mouse uterine weight but has departed from their described procedure in that (a) alcohol was the precipitating agent, (b) different standards of normal uterine weights were established (videinfra), and (c) a different method of evaluating a positive test was used. Furthermore, it is strongly felt in this laboratory that quantitations of the active substances present should depend on response to various dilutions rather than on the degree of response of the test organ.

CRITERIA FOR NORMAL AND FOR ENLARGED MOUSE UTERI

To establish values for normal uterine weights in uninjected 21-day-old albino female mice weighing between 5 and 10 grams, 98 animals were autopsied and body and uterine weights recorded (Table II). The coefficient of correlation was 0.26 ± 0.06. This coefficient is more than four times its probable

*The method used was a modification of Callow and Callow (1937): A solution of analytical reagent tannic acid is freshly prepared just before use; 3 c.c. of a 10 per cent solution of tannic acid per 100 c.c. of urine are added to a concentrated first-morning specimen which has been filtered through Reeve Angel filter paper, No. 202, and pH adjusted to 4.5-5 before the addition of the tannic acid. The mixture is allowed to stand in the cold room 16 to 24 hours and the precipitate collected into 50 c.c. conical tu[illegible] The precipitate is washed with 5 c.c. of acetone per 100 c.c. of urine vol[illegible] placed in a suction desiccator overnight. The dry powder may be stored [illegible]ss of potency; 3 c.c. of borax buffer (50 c.c. of 0.2 M boric acid (61.8 Gm. [illegible] potassium chloride (74.6 Gm./L = 1.0 M) is mixed with 20.95 c.c. of 0.2 [illegible] and diluted to 200 c.c.) is added to the amount of dry powder obtained from 100 c.c. of urine, and 5 c.c. of distilled water is added. The mixture is stirred thoroughly, and 9 drops of phenol red added to the mixture are used as an indicator. Adjustment to pH of 8-9 is made by the addition of a 5 per cent solution of sodium carbonate, and the entire mixture is allowed to stand at room temperature for no less than one hour; 9 more drops of phenol red are added and the pH now adjusted to 7-7.5, using 2 per cent acetic acid. Distilled water is then added to make a final volume of 25 c.c. This gives a solution, each 2.5 c.c. of which is equal to 10 mouse units per 100 c.c. of the original urine.

TABLE II

DATA SHOWING BODY AND UTERINE WEIGHTS IN 21-DAY-OLD FEMALE ALBINO MICE WEIGHING BETWEEN 5 AND 10 GRAMS

WT. OF ANIMAL GM.	UTERINE WEIGHTS MG.					TOTAL NO. ANIMALS	AV. UTERINE WEIGHT MG.
	2.0-2.9	3.0-3.9	4.0-4.9	5.0-5.9	6.0-6.9		
5.0-5.9	4	5	2			11	3.27
6.0-6.9	6	10	2	2		20	3.45
7.0-7.9	4	11	6	3		22	4.13
8.0-8.9	3	16	7	4	1	31	3.93
9.0-9.9	3	5	4	2		14	3.80

error and is therefore significant, although the significance is of slight degree. If the data in the group of animals weighing less than 7 grams are excluded, the correlation between the weight of the animal and the uterine weight is insignificant, so that if animals within the weight range of 7 to 10 grams are used, it is unnecessary to apply any correction factor to the uterine weights of in-

jected animals. To establish the fact that the injection of fluid alone had no effect on uterine weights, four normal mice received three times the volume of fluid used in the test in the form of normal saline. No uterine enlargement was noted.

In the series of normal control animals the average uterine weight (Table II) was 3.7 ± 0.94 mg. The uterine weight can fluctuate by chance alone within the limits of twice the standard deviation, or from 1.7 mg. to 5.5 mg. Even though the variation just given would cover 95 per cent of possible normal weights in those animals whose body weights lie between 5 and 10 grams, it was felt that a higher value, e.g., 6 mg., for the upper limit of normal would add significance to a positive result in a routine laboratory procedure. Therefore, a uterine weight of 6 mg. has been regarded as of beginning significance. The exact method of determining a positive test is presented.

PROCEDURE*

Precipitation.—Sixty c.c. of a concentrated first morning specimen of urine is filtered into a 1-litre Erlenmeyer flask. No specimen is accepted unless the specific gravity is at least 1.010. The pH is adjusted to 4.5-5, using nitrazene paper as the indicator and 75 per cent acetic acid as the acidifying agent. Eight volumes of cold alcohol which has stood at a temperature of not more than 24° C. are added. The mixture is rotated thoroughly and allowed to stand at this temperature for twelve to forty-eight hours. The active principle, which is water-soluble, settles to the bottom as a precipitate. The flask may remain at the reduced temperature for as long as a week without altering the results of the subsequent assay. The supernatant fluid is removed by suction (or by decanting if it has stood for the longer period of time), leaving a small amount behind in order to rinse out the precipitate into a 50 c.c. Pyrex conical centrifuge tube. All of the precipitate is collected into the conical centrifuge tube by use of a rubber policeman and repeated rinsings of the Erlenmeyer flask with supernatant fluid. The precipitate remains in the centrifuge tube throughout the subsequent steps of the procedure. After complete collection, it is washed twice with absolute alcohol, once with anhydrous ether, and placed in a desiccator overnight. There result a dry powder which can be stored indefinitely without loss of potency if kept dry. The active principle is prepared for assay by dissolving the powder in 15 c.c. of distilled water and adjusting the pH to 4.5-5 (as tested with nitrazene paper) using 75 per cent acetic acid. The water is allowed to stand in contact with the powder four to eight hours, and the mixture is stirred well at intervals no less than four times. If an insoluble residue remains, the clear supernatant fluid is used for injection. There is no loss of potency if this solution stands for several days, but loss of potency can occur, however, if the solution is allowed to stand as long as fifteen days at a temperature of 24° C. or less.

Whether complete precipitation is obtained even with alcohol is, of course, a debatable point. Comparison of the assays in which alcohol was used with the assays in which the direct method was used (Table I) show some discrepancy. One explanation may be incomplete precipitation; another may be that there

*The procedure here given has been slightly modified in the hands of Kleinfelter, Albright, and Griswold (1943) in that calculations are made in mouse units per twenty-four hours rather than mouse units per 100 c.c.

are substances in the unprecipitated urine which have a direct effect on the mouse uterus causing enlargement and which are removed in the various steps of the precipitating procedure. The discrepancy needs further elucidation.

Assay.—The assay is carried out on three 21-day-old mice, weighing between 7 and 10 grams. Each animal receives a total of 2.5 c.c. of the test solution prepared according to the procedure just described. Each mouse is injected as follows: 0.5 c.c. morning and afternoon of day 1; 0.5 c.c. morning and afternoon of day 2; 0.5 c.c. morning of day 3. Autopsy is performed the morning of day 4. Macroscopic enlargement of the uteri is considered a positive test. In doubtful cases the uteri are carefully dissected, pressed between filter paper to remove fluid, and weighed. The test is considered positive when the weight of the uterus is greater than 6 mg.

If only two of the three animals have uteri weighing between 6 and 7 mg., the test is not positive: but, if all three animals have uteri weighing between 6 and 7 mg., the test is considered positive. If one of three animals has a uterine weight of more than 7 mg. and the other two animals have uteri weighing less than 6 mg., the result of the assay is considered doubtful and is repeated not later than the next day. A conclusive result is usually obtained. When, according to this technique, three animals each receive 2.5 c.c. of the test solution and show no uterine enlargement, there is less than 1 mouse unit of pituitary gonadotropic substances present in 10 c.c. of the first morning specimen. When the mouse uterus is enlarged in animals which have received 2.5 c.c. of the test solution, the urine is known to contain a minimum of 1 m.u./10 c.c., or 10 m.u./100 c.c. In order to determine whether the gonadotropic content of the test solution is higher than 10 m.u./100 c.c., aliquots of this 15 c.c. of test solution are diluted from 2 to 9 times.* The assay is made with 2.5 c.c. of the diluted aliquots in the same manner as that described for the assay of the test solution.

DISCUSSION

Since the qualitative presence of pituitary gonadotropic substances can be demonstrated in instances where their concentration is high by injecting the urine directly into the test animals without preliminary precipitation, the point may well be raised whether testing for various levels is necessary. The injection of unprecipitated urine into the test animal gives a positive result only if the level is as high as 40 m.u./100 c.c. By alcohol precipitation the same volume of test solution injected is equivalent to 10 c.c. of the unprecipitated urine and, therefore, levels as low as 10 m.u./100 c.c. may be detected. For still lower values a modification of the Heller and Heller method is now used in this laboratory (Kleinfelter, Albright, and Griswold, 1943).

Using the method of concentration and assay just described, there was less than 10 m.u./100 c.c. in the urine of normal women throughout the menstrual

*In the use of three test animals a convenient table for making dilutions follows:

DESIRED ASSAY, M.U./100 C.C.	VOL. OF TEST SOLUTION NEEDED—C.C.	VOL. WATER TO BE ADDED—C.C.
30	3	6
50	2	8
70	2	12
80	2	14
100	1	9

cycle with the exception of one or two days at or near the time of ovulation. In menopausal patients any first morning specimen of urine was positive for a minimum of 10 m.u./100 c.c., and values as high as 100 to 150 m.u./100 c.c. were recorded in a few instances.

While enlargement of the uterus was the criterion of a positive test, it may be of interest that the ovarian response at the end of the 72-hour test period consisted of follicle enlargement only and corpora lutea were never seen. In addition, the vagina of test animals was potent in instances in which the level of the pituitary gonadotropic substance was of the order of 30 m.u./100 c.c. and over.

In the practical consideration of the test described, the greatest difficulty may be in obtaining animals which meet the specifications of the test. The procedure has merit in that the precipitate may be stored until such time as animals are available, and since the mortality rate of injected test animals is low, a minimum number of mice is needed.

SUMMARY AND CONCLUSIONS

1. In the method for the assay of increased amounts of pituitary gonadotropic substances in the urine the precipitation of those substances with alcohol is superior to precipitation with tannic acid.

2. Eight volumes of alcohol is probably better than four.

3. As a test animal, the mouse is more sensitive than the rat, and as a test organ, the uterus is preferable to the ovary.

4. The method used in this laboratory is presented.

The authors wish to thank Dr. Jacob Lerman for his help in the statistical evaluation of data, Dr. Hirsch W. Sulkowitch for his suggestions in the development of the method, and Dr. Rucker Cleveland for assistance in preparation of the manuscript.

DOUBLE DISTILLATION IN ONE AND THE SAME FLASK*

F. RAPPAPORT, PH.D., PETAH TIQVA, PALESTINE

THE principle of the double distillation in one flask was described by us in 1934, and was put into practice by the construction of an apparatus for the preparation of double distilled water.† The described apparatus had the disadvantage of working only half automatically, as the water supply during the process of the distillation had to be regulated continually. These circumstances have induced us to construct the apparatus, reproduced in Fig. 1,

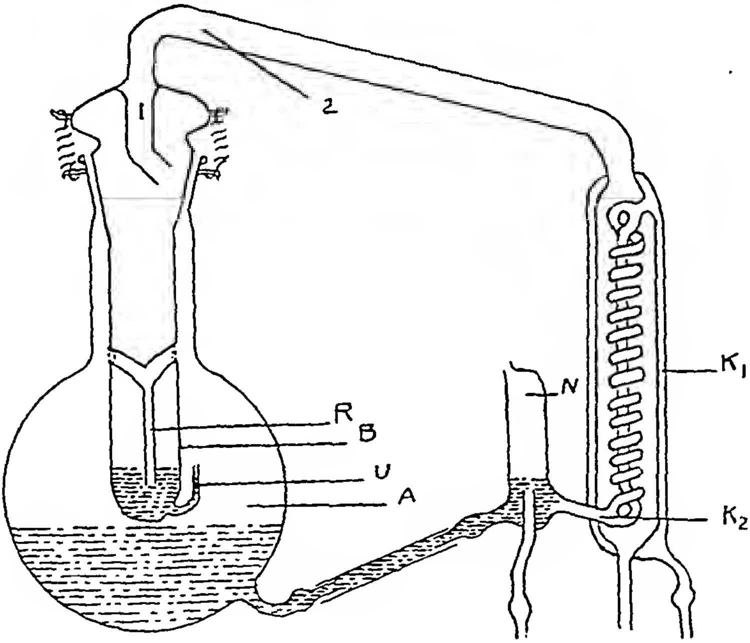

Fig. 1.

which guarantees a fully automatic double distillation. The apparatus consists of two distilling vessels (A and B), fitting into each other; A is heated by gas or electricity, B by steam created by A. The outer flask (A) is connected to a constant level arrangement (N), which allows a continuous water supply, thus replacing the water, evaporated in A. When the outer flask is heated, the steam gets into the inner distilling vessel (B) through Tube R, and from there via 1 and 2 into condenser K. By condensation in the condenser, part of the water runs down as singly distilled water. Another part, after condensation in Glass tube 1, runs back into vessel B and is condensed there, whereby the lower part of B up to the height of the drainage tube (U) is constantly filled

*From the Biochemical Laboratory of the Beilinson Hospital, Petah Tiqva, Palestine.
Received for publication, April 8, 1943.
†Rappaport, F.: Mikrochem. 15: 302, 1934.

with water. The constant heating by the steam, coming in from R, and the heat in flask A effect a renewed distillation. The drainage tube (U) acts in a way as a valve, as the condensed water which does not reach a second distillation flows off, thereby obtaining a constant pressure and regular boiling. The inner vessel (B) is connected by way of ground joint and elastic wire spirals with A, and *is directly melted to the double condenser,* K_1 *and* K_2.

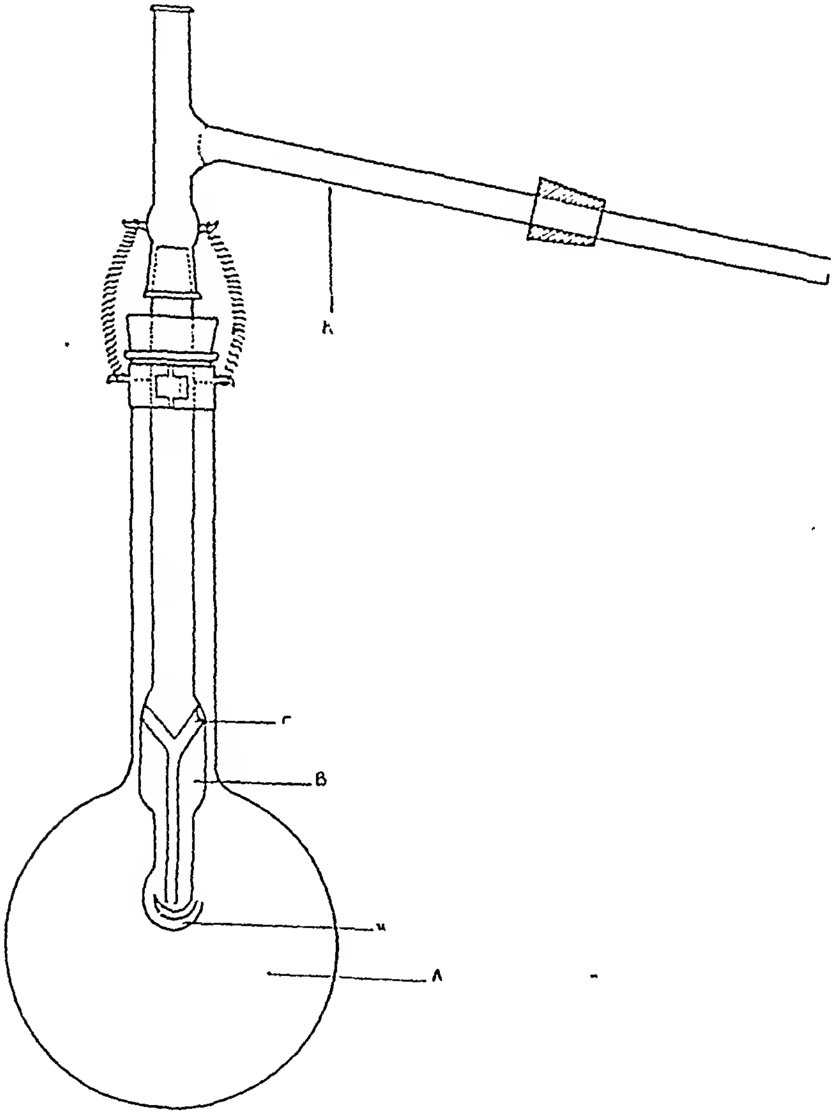

Fig. 2.

Thereby the apparatus becomes very handy and can be fixed on a stand. This apparatus supplies, provided appropriate dimensions are taken, approximately 1500 c.c. per hour. The water gained this way has a conductivity of $K = 1.5$ .10—6.

The principle of the one-sided double distillation can also be used for the rectification of different organic solvents with the aid of the apparatus,

reproduced in Fig. 2. The solvent is distilled from the outer round flask A into the inner vessel (B). Through continual heating by the steam coming through the Y-shaped tube (r), and also through steam present in bulb A, a second distillation into the inner vessel is effected. The water vapor gets into the distilling column (K) which is supplied with a thermometer and connected to a condenser. The column is connected by ground joint to vessel B which, according to requirements, can be fitted into flasks of different sizes by means of suitable stoppers. At the lower end of tube B a drainage tube (*u*) enables the condensates to run off during the distillation, thus effecting constant pressure in both vessels. The same principle of inserting two bulbs into one another

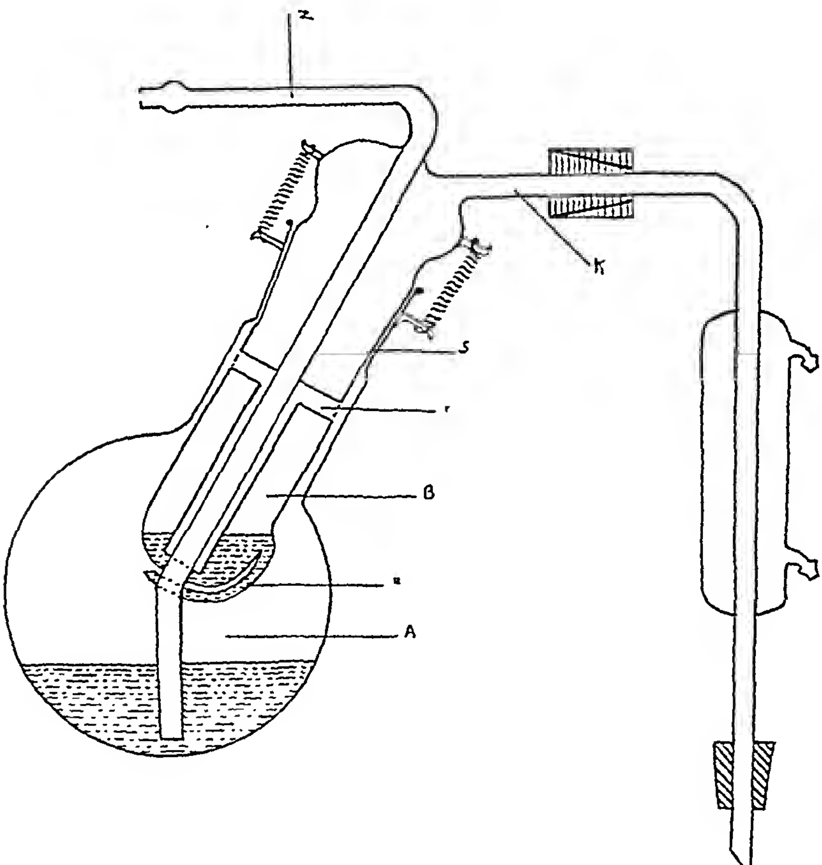

Fig. 3.

can also be profitably applied to steam distillation. (See Fig. 3.) Through tube z steam is led into the liquid that is immiscible with water in flask A. From there the steam reaches B over tube r. The condensing steam collects again on the bottom of the inner flask which communicates through drainage tube U with the outer flask and thereby stands under constant pressure. The oil-loaded steam, further produced in B, leaves through lead k into the condenser. This apparatus too may be furnished with stoppers instead of ground joints, and can thereby be connected with flasks of different sizes.

MICRODETERMINATION OF ACETONE AND DIACETIC ACID IN BLOOD*

F. RAPPAPORT, PH.D., AND B. BANER, PETAH TIQVA, PALESTINE

THE following method, which is based on the method of M. Ljungdahl,† allows the determination of acetone bodies accurately and quickly in 0.2 c.c. blood or serum by means of a simple and easily handled apparatus. The distillation apparatus (see Fig. 1) consists of three parts:

(1) The distilling flask (A), which is a 50 c.c. Erlenmeyer flask connected to the distilling headpiece by a ground joint.

(2) The distilling headpiece. When in use the connection is secured by a pair of elastic springs (*f*). The headpiece consists of a glass tube, the ends of which are bent downwards at an obtuse angle. The shorter side (a) is widened at its end to a semisphere (h) and is ground on to the distilling flask. The second and longer side (b) serves as a dropping tube and is surrounded by an external condenser tube for condensing the distillate. If there is no running water available, it is sufficient to fill the condenser with cold water once for each determination. The washing of the apparatus is done through the side tube (C), which is attached to the middle part of the distilling top piece. This tube (C) is extended to a capillary (D), running parallel to the axis. During the distillation, the tube is closed by a cork stopper. The glass rod, which is sealed on to the top of the semispheric ground joint and which ends closely above the water seal of the distilling flask, prevents boiling over.

3. The receiving vessel (B), a 50 c.c. Erlenmeyer flask, which is connected to the apparatus by a double clamp (S). One clamp holds the vessel; the second one is fixed to the condenser and can be moved so that the end of the distilling apparatus, according to requirement, is immersed into the received liquid or ends freely above it. To facilitate work during the distillation a hinge is fixed on the clamp carrier, thereby putting the flask in an oblique position and making it possible to shake it backwards and forwards as well.

REAGENTS

1. Diluted phosphoric acid solution. Two to three drops concentrated H_3PO_4 to 100 c.c. distilled water.

2. Iodine solution. 0.75 c.c. 1:10 N-Iodine solution and 5 c.c. 20 per cent sodium hydroxide are filled up to 50 c.c. with distilled water. (Prepared daily.)

3. Potassium iodide in crystals.

4. Concentrated hydrochloric acid diluted in equal parts with water in a dropping bottle.

5. 1:1000 n-sodium thiosulfate solution.

6. 0.25 per cent starch solution.

†Eine Mikromethode zur Bestimmung des Total-Acetons im Blute Biochem. Ztschr. 96: 345, 1919.

PROCEDURE

Before beginning the determination, the distilling apparatus is rinsed with distilled water through the side tube (C) and the opening is closed quickly with the stopper, so that a small column of liquid in the capillary (D) closes the latter against the inside of the distilling headpiece. The ground neck part of the flask (A) is moistened with a bit of water. By means of the elastic springs the flask is fixed on the semisphere of the distilling headpiece. On the other side of the apparatus a flask (B) is clamped. Then water is heated in A and distilled into B until cleanness of the apparatus is fully assured. Now the analysis is started with the determination of the "blank value."

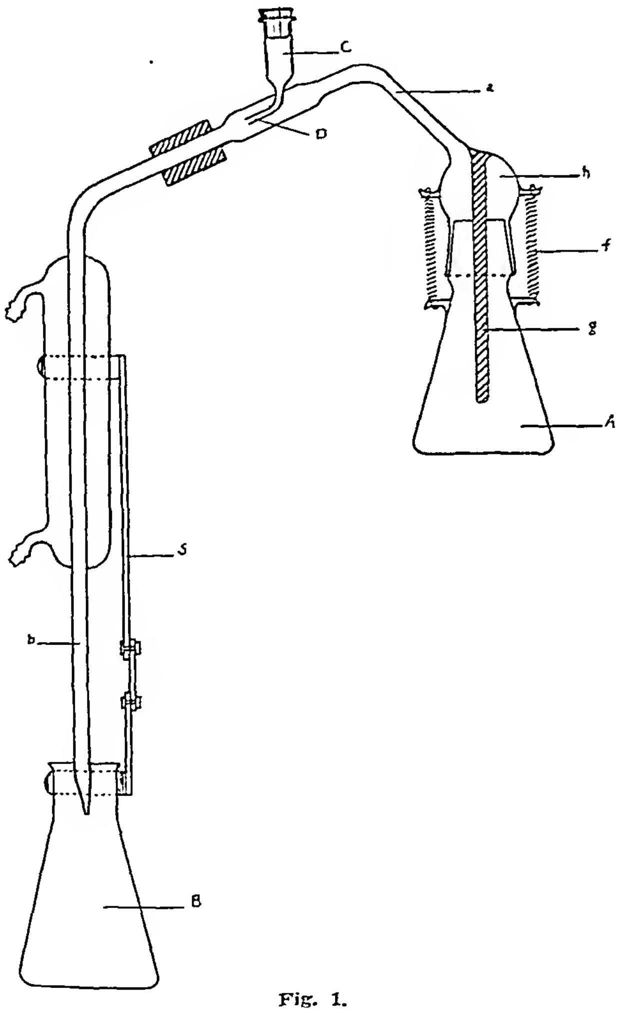

Fig. 1.

As receiving flask, flask B containing exactly 2 c.c. of the iodine solution (2) is fixed to the apparatus so that the distilling tube is immersed in the fluid. On the other side a distilling flask (A) containing 4 c.c. phosphoric acid is fixed in the manner explained above, and is heated by a small flame. The phosphorie acid is to be measured in a small, narrow-measuring cylinder in order to avoid mistakes arising from traces of alcohol, ether, or acetone left in the pipettes. When the contents of the flask have boiled for three minutes, flask

B is pushed down, so that the distilling tube is no longer immersed and goes on boiling for only another minute. Eventually distilled water is rinsed through the opening (C).

Some crystals of potassium iodide, hydrochloric acid, and a few drops of starch solution are put into flask B. It is shaken and then titrated with 1:1000 n-sodium thiosulfate solution. The value thus found is the "blank value." It must be equal to the value found when adding potassium iodide, hydrochloric acid, and starch solution to 2 c.c. of iodine solution in the same way in a receiving flask and when titration is carried out without any distillation. When this is not the case, the distillation must be repeated. Once the "blank value" is found, the actual determinations can be carried out, one after the other. This is done by adding, using the precautions necessary in exact analytic determinations, 0.2 c.c. of the blood or serum to be examined to the measured amount of phosphoric acid in flask A, which are attached to the apparatus in succession. Distillation is carried out just the same as described for the determination of the "blank value." Titration of the iodine solution in flask B, carried out subsequently, gives the full values.

CALCULATION

"Blank value" minus sample value multipled by 4.83 gives the acetone content in mg. per 100 c.c.

Example:

Blank Value	2.72
Sample Value	1.34
Difference	1.38

$1.38 \times 4.83 = 6.6654$ mg. per 100 c.c. acetone.

The figures given in the accompanying tables prove the utility of the method.

1. Amount of c.c. n/1000 thiosulfate solution required with diluted acetone solution.

Without Distillation	With Distillation
0.45	0.44
0.90	0.91
1.34	1.33
1.79	1.77

2. Blood and serum to which measured amounts of acetone were added always gave values that corresponded to the amount of acetone found in the blood plus that added to it.

Example:

Blood	0.78 c.c. n/1000 of thiosulfate solution
Acetone Solution	1.34 c.c. n/1000 of thiosulfate solution
Calculated Amount	2.12 c.c. n/1000 of thiosulfate solution
Blood Plus Acetone Solution (Value Found)	2.10 c.c. n/1000 of thiosulfate solution

SUMMARY

A method is described which allows the determination of the content of acetone in 0.2 c.c. blood or serum with great accuracy and a simple apparatus.

This work was begun in Vienna and completed in Palestine.

BOOK NOTICES

Chemotherapy of Gonococcic Infections*

TREATMENT of gonococcic infections with the sulfonamide drugs is presented from the standpoint of a streamlined program of practical value. Choice of drugs, dosage, and toxicity are fully discussed. Special mention is made of the infectious carrier and the sulfonamide resistant case. Various methods of treatment such as fever therapy combined with a sulfonamide and vaccine combined with a sulfonamide are discussed, as are treatments of specific complications.

Of particular value to the busy practitioner is the omission of discussions of history, bacteriology, pathology, and endoscopic examination and treatment.

The problem of diagnosis and determination of cure in both male and female are stressed. At the end, certain investigative problems are briefly presented, and case outlines are given to illustrate points in diagnosis, treatment, and complications.

The book has a high practical value to the practitioner as well as to the specialist, in its adequate, concise presentation.

Blood Groups and Transfusion†

THE third edition of Dr. Wiener's book *Blood Groups and Transfusion* has much new material, necessitated by the many advances in whole blood and plasma transfusion, as developed in the last few years. The presentation is very comprehensive. It includes discussion of blood groups and technique of grouping, selection of donors, indications for transfusions, methods of transfusion of whole blood, plasma, and serum, reactions and complications, and the organization and use of blood banks. There is a chapter on the history of transfusion, and sections are devoted to the heredity of blood groups, the newly recognized Rh factor, group-specific substances in organs and body fluids other than the blood, medicolegal application of blood tests, and technique for the identification of blood stains. There is a very interesting chapter on anthropologic studies of blood groups and on evolution of the human blood groups.

This volume should have a wide field of usefulness.

The Physiological Basis of Medical Practice‡

SINCE its first printing in January, 1937, Best and Taylor's *Physiological Basis of Medical Practice* has had three American editions, one Spanish, one Portuguese, and has had a total of twelve printings. Numerous recent advances in the application of the physiologic principles to clinical medicine, many of which have been occasioned by the exigencies of war, have necessitated many additions throughout the book. As formerly, the volume is primarily a work on applied physiology, useful not only as a text for medical students but as a reference volume for clinicians.

*Chemotherapy of Gonococcic Infections. By Russell D. Herrold, B.S., M.D., Associate Professor of Surgery (Urology), College of Medicine, University of Illinois, Chicago, Illinois. Cloth, 137 pages, $3.00. The C. V. Mosby Company, St. Louis, 1943.

(Canada); Professor and Head of Department of Physiology; Associate Director of the Connaught Laboratories; Research Associate in the Banting-Best Department of Medical Research, University of Toronto, and Norman Burke Taylor, M.D., F.R.S. (Canada), F.R.C.S. (Edin.), F.R.C.P. (Canada), M.R.C.S. (Eng.), L.R.C.P. (Lond.), Professor of Physiology, University of Toronto. Third Edition. Cloth, 1942 pages, $10.00. A William Wood Book. The Williams & Wilkins Company, Baltimore, 1943.

Allergy, Anaphylaxis and Immunotherapy*

THE contents of Ratner's book, *Allergy, Anaphylaxis and Immunotherapy* is better described in the subtitle, "A Treatise Presenting the Fundamental Principles and Practice Governing the Use of Antisera, Vaccines, Toxoids, Blood Transfusions, Blood Substitutes and Sulfonamides, in the Prevention and Treatment of Infectious Diseases and of the Allergic Phenomena Resulting From Their Use."

It may be described as a book on immunotherapy with homologous and heterologous sera, vaccines, and sulfonamides, with the discussion of allergic and other responses. The analysis of experimental work in the field under discussion, including the author's own contributions, is splendidly arranged and completely up-to-date.

The book will be of great value to allergists, immunologists, serologists, and is especially opportune because of its usefulness to all physicians who have occasion to give whole blood or plasma transfusions.

There is a section dealing with specific immunotherapy in the various infectious diseases.

CORRESPONDENCE

In view of the need for pathologic material in under-graduate and graduate education, the Committee on Pathology of the National Research Council urges that all who have suitable anatomic specimens forward them to the Curator of the Army Medical Museum, Washington, D. C., for correlation and distribution to other central agencies and to teaching institutions. Material from the following is particularly wanted: the malarial diseases, bacillary dysentery, endamebiasis, the schistosomiases, filariasis, the trypanosomiases, the relapsing fevers, the leishmaniases, the rickettsial diseases, yellow fever, cholera, plague, and yaws. On application to the Curator, arrangements for transportation will be made.

CLINICAL AND EXPERIMENTAL

THE PRODUCTION OF STAPHYLOCOCCUS ANTITOXIN*

James B. Weaver, M.D., Mary Whelan Tyler, M.D., and Doris K. Schuerman, A.B., Kansas City, Kan.

THE tissue, or tissues, responsible for the production of staphylococcus antitoxin are not known, but it is generally assumed that such production takes place somewhere in the hemopoietic system. In an effort to throw some light on this problem, the authors have done two types of experiments. First, various components of the hemopoietic system were "blocked out" in experimental animals and the immune reaction of these animals to staphylococcus toxoid as antigen was observed. Second, extracts from various tissues of immunized animals were examined for the presence of antitoxin as indicated by the titer of antihemolysin.

METHODS

White rabbits of five to six pounds each were used in all experiments. Stimulation of antibody production was produced by subcutaneous injection of Lederle's staphylococcus toxoid three times a week, the initial injection being 0.1 c.c., and the dosage increased by 0.1 c.c. at each injection until a total of 1 c.c. was given at one time. The injection period, therefore, covered a little more than three weeks. Titers of antihemolysin were determined twice a week. This procedure was followed in each series of experiments, and in some series total leucocyte and differential counts and hemoglobin determinations were done daily or three times a week as indicated. In most cases the animals were sacrificed at the end of the study period, and sections of bone marrow from typical long and flat bones, spleen, and liver were taken for microscopic study. The results of the study of the microscopic slides will be reported in another paper.

CONTROLS

A series of six control animals was run, and, in addition, two controls were studied concurrently with each series of experiments, making a total of nineteen. The results obtained in each individual series were compared against this relatively large number of control animals.

Seventeen of the 19 control rabbits had no initial antibody titer, while two had 0.6 international units of antihemolysin per c.c. before toxoid injections were begun. These rabbits varied somewhat in the length of time required for the response to stimulation, the antibodies appearing in the serum from the eleventh to the twenty-ninth day after the first injection, the average for the whole series being the eighteenth day. The highest concentration of antibodies in the serum was reached at intervals between the eighteenth and the fortieth day, the average being twenty-two.

BENZENE

It has long been known that benzene has a depressant action on the bone marrow, affecting primarily the elements having to do with the formation of the leucocytes. Kracke[1] has shown that benzene given subcutaneously has a marked depressant action on the white blood cells, particularly the granulocytes, and that the erythrocytes are little affected. This is true, except that there is a definite drop in hemoglobin after benzene injections have been continued for some time.

The authors have observed that rabbits have a variable individual resistance to this substance, so that many of them died quickly with a very low leucocyte count, or in an apparently very toxic condition when the white cell count was not at what could be considered a critical level. Autopsy on these animals showed nothing grossly abnormal. The final series consisted of 9 rabbits which survived long enough to receive the full dosage of toxoid. In addition, there were 4 rabbits which received from 0.5 to 0.7 c.c. of toxoid at one time. The general procedure in this series was to inject 1 c.c. of benzene per kilo of body weight subcutaneously daily until the leucocyte count reached 3,000 or less, and then to inject at intervals the amount of benzene necessary to keep the leucocytes at approximately 2,000. When the leucocytes had been sufficiently depressed, toxoid injections were begun. It was not uncommon for the level of the total white cells to reach relatively high levels, probably due to an effort on the part of the bone marrow to overcome the rapid destruction brought about by the benzene.

Of the 9 rabbits in this series, 7 had no initial titer and did not begin to show serum antibodies until twenty to forty-one days after toxoid injections were begun (average, twenty-seven days), and reaching the height in from twenty to forty-eight days (average, twenty-six). Three never did develop a titer. Chart 1 shows four graphs which are typical of the results obtained in this series. Observe the extent of the depression of the leucocytes produced by benzene injections, particularly in the case of Rabbit 12, and the delay in the appearance of antibodies, as well as the small total amount of antihemolysin present. As shown in Chart 2, in which the average curves of serum antihemolysin for both controls and benzene series are plotted, there is a distinct delay in the appearance of antibodies in the benzene series, and the total content

is much lower than that of the control series. Rabbit 12 shows the combined effect of benzene and toxoid very well. This rabbit was studied for somewhat over three months after benzene injections were begun. The leucocyte count was kept at a very low level most of the time, with the occasional elevations mentioned previously. This rabbit had a negative titer for forty-one days after toxoid injections were begun, in spite of the relatively heavy dose of antigen given. In this case the total dose was carried to 1.5 c.c. and an additional 1 c.c. was given at weekly intervals for two injections. It was not until a week following the last injection that a positive titer was demonstrated. The rabbit died with a leucocyte count of 200.

At autopsy these animals showed nothing grossly abnormal except for a very pale bone marrow. Fig. 1 shows bone marrow from normal control rabbits. In contrast, Fig. 2 shows the hypoplastic bone marrow produced by repeated injections of benzene.

CARBON BLOCK

In an effort to block the reticulo-endothelial system, an 8 per cent suspension of Higgins Waterproof India Ink was injected intravenously and intraperitoneally daily in amounts of 20 c.c. by each route. Injections were continued throughout the study. A suitable interval, based partly on the elevation of the total white count but principally on the appearance in the peripheral circulation of considerable numbers of nucleated red cells, was allowed to elapse before toxoid injections were begun. From 200 to 350 c.c. of the suspension were injected, as a rule, before giving toxoid. Cannon et al.[2] have pointed out the importance of continuing the daily injections, particularly intravenously, throughout the period of study and giving the blocking material in sufficiently large amounts to overcome the tendency to stimulation produced by smaller amounts. As much as 1,220 c.c. of the 8 per cent suspension of ink has been given a rabbit during the period of study. Cannon[2] has shown that the amount of fluid is not significant, for he produced no effect in the rabbits to which he gave isotonic saline by the same routes and in the same quantity as his blocking material.

Of the 9 rabbits used in this series, 7 had no initial antihemolysin titer, and the average time of the appearance of antibodies after toxoid injections was twenty-three days (ten to forty). In these, the maximum titer was obtained on an average of twenty-seven days (fourteen to fifty). Chart 3 shows curves for total white cells and antibody content obtained in four typical animals of this series. Note the marked elevation of the total leucocyte count, the delay in appearance, and the low content of antibodies in the serum. Differential counts showed nothing of particular significance except the appearance of large numbers of nucleated red cells and phagocytosis of carbon particles by the polymorphonuclear leucocytes and monocytes. Hemoglobin showed a steady and marked drop as the block was continued. At the end of the experimental period, the hemoglobin content was well below 7 Gm. per cent in all cases.

Chart 2 shows composite curves plotted against the controls. It may be observed that the curve for the blocked animals is much flatter than that for the controls, that the antibodies appeared later and did not rise to so great a quantity. Of the two rabbits which showed an initial titer, one (39) showed a

diminution in serum antibodies after the ink injections were begun, while the other (42) showed a steady rise.

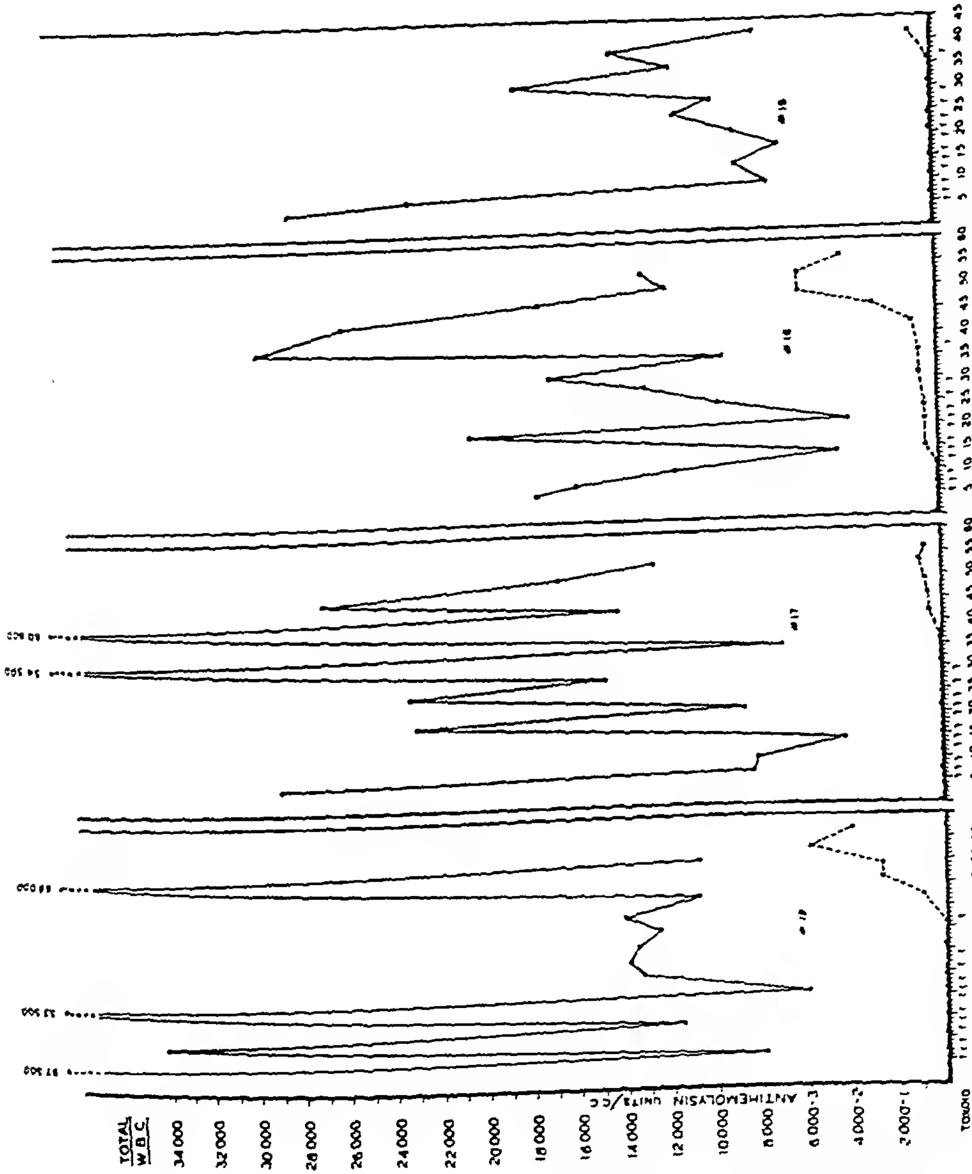

Chart 3.—Total leucocyte count and serum antihemolysin in four typical rabbits in which the hemopoietic system had been blocked with carbon.

The total leucocyte count in the blocked animals was usually relatively high, being well above that of the control animals and increasing to as much as 96,000 in some instances (Chart 3). The animals were killed after a definite decline of serum antibody content occurred, and at autopsy all lymphoid tissue was found to be stained black, the liver and spleen were greatly hypertrophied, the spleen having increased in weight approximately ten times that of the normal animals. The bone marrow was intensely black, the omentum thickened and enlarged. Grossly, the kidneys showed no evidence of having taken up carbon.

SPLENECTOMY

Splenectomy was performed on 11 animals. Three weeks were allowed to elapse following operation before toxoid injections were begun, in order that the

animals might fully recover from the effects of the surgical procedure. Chart 4, where four typical curves are shown, and Chart 2 show the results obtained. It may be noted that the curve for antibody production is similar to that of

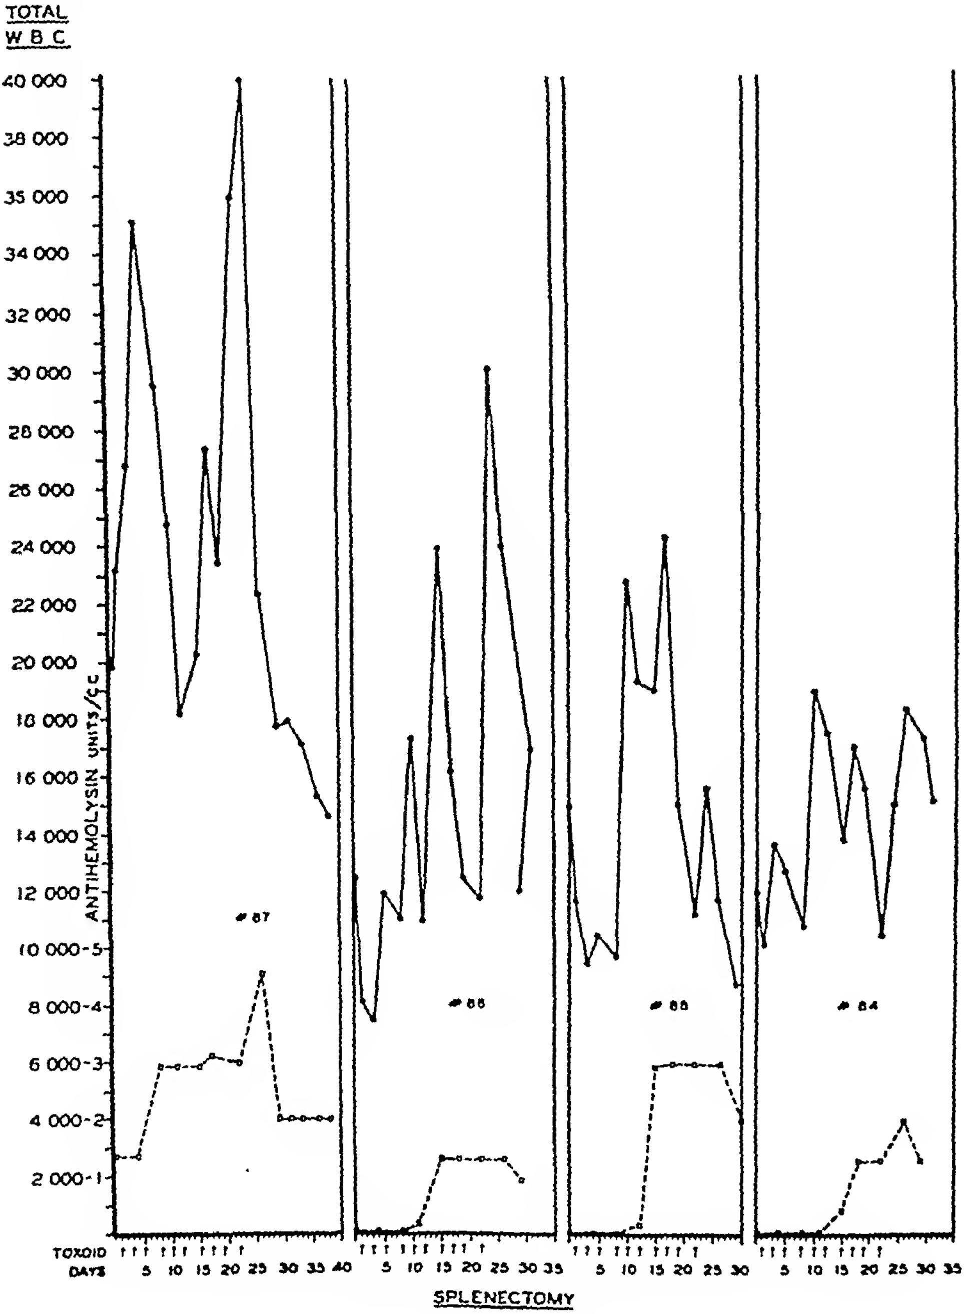

Chart 4.—Total leucocyte count and serum antihemolysin in four typical rabbits from which the spleens had been removed.

the controls in height and shape, differing only in the time of the first appearance of antibodies in the serum. In case of the splenectomy series, antibodies appeared sooner. Analysis of the individual results shows that antibodies appeared

in the serum in two to sixteen days, with an average of eleven days, and the height was reached from the tenth to the twenty-third day (average, nineteen days).

In order to rule out the effect of surgical procedure, nephrectomy was performed on four rabbits. Toxoid injections were begun after a three-week period. The production of antihemolysin showed no particular difference from that in control animals.

Chart 5 is a composite of all curves and shows very clearly the delaying effect of benzene and carbon block on the appearance of antibodies in the serum.

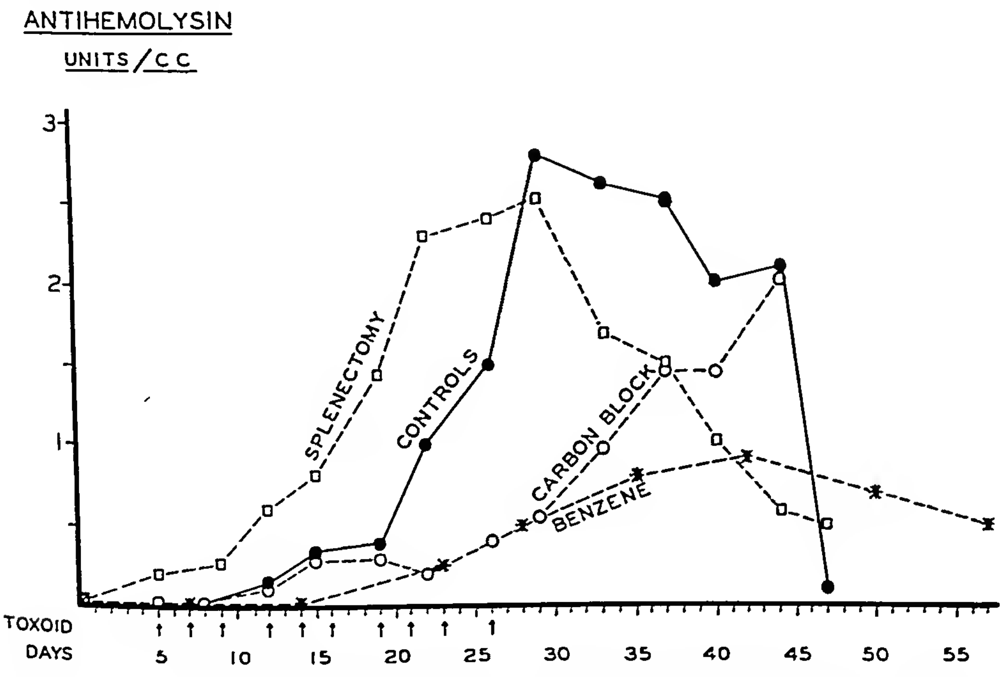

Chart 5.—A composite of all curves showing the depressing effect of carbon and benzene block and the apparent transitory stimulation due to splenectomy.

TISSUE EXTRACTS

It was thought that it might be interesting to study the organs rich in lymphoid tissue for their antibody content. Cary[3] and Motahashi[4] determined tissue antibodies after injecting foreign erythrocytes, by means of extraction with 50 per cent glycerin (14 to 1 dilution) in the incubator for five to six days. This procedure was followed, but we were unable to demonstrate antibodies in the spleen, bone marrow, or liver of sacrificed animals with appreciable known quantities of antitoxin in their blood serum. Undoubtedly this was due to the relatively large dilution recommended. The following procedure was therefore devised.

The animals were exsanguinated and the tissues removed immediately after death, placed in the freezing unit of the refrigerator for twenty-four hours, then pressed through a fine sieve. Two grams of tissue were extracted with 2 c.c. of 0.85 per cent saline for five days in the refrigerator. The tubes were then

centrifuged at high speed, and the supernatant fluid was used for the antihemolysin determinations. The procedure from this point was the same as that used for serum antibody determinations.

By this means we have demonstrated the presence of antihemolysin in bone marrow in 19 of the 56 rabbits in which antibodies were present in varying

quantities in the serum. Table I gives the results. Liver, spleen, and bone marrow were studied, and in a few cases, muscle tissue determinations were made as controls. As can be seen in Table I, antibodies were demonstrated only in bone marrow, with the exception of two instances in which small amounts were found in the spleen.

COMMENT

Several factors must be considered in an evaluation of the preceding results. A marked variation in immune response was noted in many of the experimental animals. The cause of this phenomenon is not known, but is usually ascribed to individual characteristics (whatever they may be). The carbon block procedure is not considered to be too efficient. The effect of the carbon was a marked stimulation of leucocyte production instead of depression, and the absorption of carbon by component cells to neutralize their activity, was relied upon to effect the block. It can be readily seen that in this method it is almost impossible to keep the stimulation-block mechanism in complete balance, and it is very easy for the pendulum to swing to the stimulation side.

Benzene is considered a more efficient agent than carbon, but its action is more selective as it apparently affected only the bone marrow. However, its efficiency was somewhat impaired as a result of the toxicity of the drug. When too much benzene was given, the animal died, but if too little was given, bone marrow stimulation ensued.

Splenectomy is considered efficient. The operative procedure might have enhanced antibody production. However, this factor seems to have been ruled out by the results obtained after nephrectomy.

The tissue extract experiments are considered moderately accurate. Care was taken to thoroughly exsanguinate animals so that antibody concentration in the serum would not be measured. The results in Table I are evidence of the success of the method.

It may, therefore, be said that while no definite conclusions may be drawn, yet there is some evidence that staphylococcus antitoxin is produced in the bone marrow.

HUMAN PLASMA AND SERUM TOXICITY

David State, M.D.,* Minneapolis, Minn., and
Milton Levine, M.S., Ph.D.,† Chicago, Ill.

REACTIONS have been reported for both serum and plasma following intravenous administration in humans and animals. The reports are, however, at variance as to the frequency of their occurrence and their severity. Many observers prefer plasma, whereas others by continued use seem to prefer serum for human transfusions. The literature on the subject yields many conflicting observations on the relative merits of the two fluids.

Strumia and his co-workers[1] are firm believers in the value of plasma because of the reactions encountered with serum: "we continue for several reasons[2] to give preference to plasma." McGuiness, Stokes, and Mudd[3] prefer plasma because of the severe reactions observed following the use of lyophile immune serum. Ravdin[4] states, "The frequency with which reactions have occurred following the injection of lyophile serum makes us hesitate to suggest the general acceptance of this material." Meakins[5] is but one of many others reporting serum transfusion reactions.

On the other hand, Levinson and his co-workers[6] continue to use serum and have no doubts as to its safety. "No reactions were observed or need be anticipated if serum is properly prepared." Mellanby[7] urges the use of serum, as do also Self and Scudder.[8] For ease in preparation, the latter prefer serum despite numerous reactions following such transfusions.

It would seem, therefore, that serum is suspected of causing more reactions than plasma, but that some workers prefer serum for other considerations than that of reactions, and these workers either deny that reactions should occur[6] or are of the opinion that the reactions are not important.[8]

The references to plasma reactions are not as copious as for serum. Because of this, many workers have assumed that reactions with plasma do not occur. However, such reactions have been reported. Stephenson and co-workers[9] described a plasma reaction with chills and fever. Self and Scudder[8] observed 4.9 per cent reactions with type specific liquid plasma, 8.2 per cent with pooled liquid plasma, and 5.6 per cent with dried pooled plasma, in a small series of cases. Elliott[10] reported 482 injections of plasma with three reactions. Polayes[11] and Levine and State[12] have given detailed case studies of plasma reactions.

There are many reports of reactions without detailed description as to number or type. Mahoney and his collaborators[13] simply state that, "there have been very few reactions," which indicates that they did observe them. Strumia et al.[14] talk about a "mild urticarial reaction," but conclude that the use of plasma "is simple, safe, and free of reactions."[2]

Received for publication, May 10, 1943.

It is probably correct to conclude that reactions do occur with both serum and plasma. As to serum, early experimentation may explain part of its excessive toxicity. From the time Bowditch[15] first perfused the frog's heart with serum in 1871, much work has been done on serum and plasma transfusion and perfusion in animals. Moldovan[16] in 1910 reviewed the literature up to that period and concluded that serum was more toxic than plasma. He attributed this to a "fibrin ferment" formed in strictly fresh defibrinated blood or blood serum. This ferment was destroyed in about half an hour. For later reviews on the subject, the reader is referred to the papers by Janeway, Richardson, and Park,[17] and Amberson.[18]

During the course of several thousand plasma transfusions at the University of Minnesota Hospitals, we observed reactions frequently enough[19] to invite more detailed observation and experimentation. Since we had been using group specific plasma routinely in the hospital because of ease in preparation, it was possible to make our observations without the complicating factors involved in pooling. In addition, pooling was not practiced routinely, because the main reason for doing so (neutralization of antibodies) had in our opinion never been conclusively established as necessary.

REACTIONS DUE TO A AND B SUBSTANCES

Shortly after the decision was made to study these reactions experimentally, we[12] observed a reaction to plasma in a patient who had been given a routine transfusion on the surgical wards. This patient, G. H., was of blood group O. He developed chills, severe dyspnea, and cyanosis following the intravenous administration of 150 c.c. of undiluted group A plasma. The possibility of incompatible agglutinins in donor plasma was eliminated, since the red cells of the recipient were of group O and hence inagglutinable by the administered plasma. By all theoretical immunologic considerations this group A plasma should have been innocuous. We decided to skin test the patient with the plasma. Previously we[19] had suggested the possible value of such a procedure, knowing well the difficulties of skin tests in general and yet recognizing its invaluable aid in testing for sensitivity to tetanus, pneumococcus, diphtheria, and other antisera.

We found that not only did this patient give a positive skin test with the reacting plasma, but also with three other group A plasmas and one AB plasma, but not with B or O plasmas. The patient was subsequently given 100 c.c. of another group A plasma with resultant chills, cyanosis, and dyspnea. Group O and group B plasmas given intravenously gave no reactions.

From the above and similar cases, we assumed some relationship between the reactions and the blood group of the administered fluid.

Moss[20] in 1910 demonstrated that the hemolytic action of A serum on B cells can be prevented by mixing A serum with B serum. Schiff[21] later found that serum of group A blood contained soluble A substance which seemed to have the same antigenic structure as A substance in the red cells. Levinson and his co-workers[22] found that mixing of A and B sera caused neutralization of the isoagglutinins in both sera. Lubinski[23] attributed this phenomenon to a nonspecific factor, but Aubert and his associates[24] ascribed the neutralization to the dissolved A and B substances found in serum and plasma of the corre-

sponding blood groups and were able to confirm this neutralization by pooling and by the addition of purified A and B substances prepared by Witebsky and his co-workers.[25]

We felt that these dissolved A and B substances might be responsible for the phenomena described. Fortunately we were able to obtain the purified A and B substances from Witebsky, and we used this material to check our hypothesis.

We can summarize our findings as published or still in press. Patients sensitive to the A or B plasma by skin tests with repeated A or B plasmas and some AB plasmas are also sensitive by skin test to the purified substance. These patients are also sensitive to group A or B plasma or AB plasma administered by the intravenous route. They have reactions following the intravenous administration of the purified A and B substances. As control measures, all plasmas are tested for sterility. Some have been divided into two parts, part going to a sensitive individual with a resulting reaction and part to a nonsensitive individual of the same blood group without a reaction. Individuals sensitive to one group specific substance do not necessarily show sensitivity to the other group specific substance, although we have one instance of a patient being sensitive to both.

Patients displaying sensitivity do not necessarily have an allergic history. There does not seem to be any correlation between the amount of antibody present in the recipient and his sensitivity to the factors. However, only those individuals who are in the blood group in which the specific antibody is found corresponding to the specific A or B substance show sensitivity. Not all individuals show this sensitivity even if they have the antibody.

Are the reactions described as being due to the A and B factors important? Are they severe enough to be significant? In most of the cases, the reactions were severe enough to cause great discomfort to the patients. In all our cases we neglected to wait for a natural outcome of the reaction, since we have found that adrenalin relieves the symptoms. It is difficult to say whether any would have proved fatal without the adrenalin. We were not justified in withholding the adrenalin to find out. The severity of any reaction depends upon the reacting material and on the condition of the patient. A reaction which would not disturb a normal individual might kill a patient in a precarious condition.

A case which illustrates the practical importance of the phenomenon follows:

A. J., a woman, age 56, blood group O, had a cholecystectomy for chronic cholecystitis on November 19, 1942. Following the injection of the spinal anesthetic (10 mg. of nupercaine between L_1 and L_2), the blood pressure fell from 170/90 to 100/60. The pulse, however, remained between 70 to 80 per minute. She was given 30 mg. of ephedrine and 0.2 c.c. of neosynephrin intravenously without elevation of the blood pressure. The spinal anesthesia was supplemented with cyclopropane. For the first hour of the operation, the blood pressure remained at about 100/60 and the pulse between 70 to 80 per minute. When the blood pressure failed to rise, the patient was given 500 c.c. of pooled equal parts of A and B plasma intravenously. Ten minutes after the plasma was started, the blood pressure fell from 100/60 to 80/40 and the pulse rose from 80 to 110 per minute. It was then noticed that the patient had developed a generalized giant urticaria. The plasma was stopped, the patient was given 500 c.c. of 5 per cent glucose in saline and 3 c.c. of metrazol intravenously

with elevation of the blood pressure to 110/60 and a fall in the pulse rate to 90 per minute. The skin test to the administered plasma was strongly positive (on the operating table). Subsequently the patient was skin tested and found positive for numerous B plasmas and the purified substance. Skin tests and intravenous administration of type A plasma were without incident.

This case indicates that reactions occur under anesthesia and that they may be serious if unrecognized.

Following the recognition of the factors responsible for some plasma reactions, we were interested in the effect of pooling on the production of these reactions. Although our experience with pooled serum or plasma in cases sensitive to the A and B substances is less extensive than with group specific plasma, we have some results which are indicative. In one case previously reported,[26] the patient was sensitive to both the A and B substances. Skin tests to plasma pooled in the ration of 5:1, 2:1, and 1:1 (A:B plasma) were positive. This confirmed previous observations on other patients.[27] This patient developed a reaction to a transfusion with A plasma but not with O plasma. We then obtained a batch of pooled serum from the Human Serum Center at the University of Minnesota. The pool contained 8 group O, 8 group A, 3 group B, and 1 group AB sera. It gave a positive skin test, and after 10 c.c. had been given intravenously, the patient developed a generalized erythema, epiphora, dyspnea, rapid pulse, and a fall in blood pressure. The same serum pool gave no reaction in a nonsensitive individual.

The effect of pooling on the response to administration of the plasma in sensitive individuals was studied in a case previously reported. In this patient, a reaction occurred following transfusion of a pooled specimen of equal parts of A and B plasma, which also gave a positive skin test. The patient was only sensitive to the B plasma.

It may be that patients sensitive to a single factor may not show as marked a reaction to pooled plasma or serum due to the dilution of the A and B substances. Where the patient is sensitive to both factors, dilution would play less of a role. Neutralization of the A and B factors, in the proportions tried, does not occur in pooled specimens of plasma or serum; hence pooling is not a sure method of preventing reactions due to these substances.

REACTIONS DUE TO FACTORS OTHER THAN THE A AND B SUBSTANCES

We have evidence that reactions may occur because of factors other than the A and B substances. We have reported three cases of such reactions previously.[26] We feel that the following may be the cause of reactions when the A and B substances are not involved:

1. The presence of allergens in the plasma or serum.[28]
2. The presence of reagins in the plasma or serum.[29, 30]
3. The presence of pyrogens.
4. The presence of immunologic factors as yet unknown.

To illustrate transfusion reactions due to factors other than the A and B substances, we present the following cases observed at the University Hospitals in Minneapolis:

Case 1.—F. C., a woman aged 44, of blood group O, had lower and middle lobe lobectomy of the right lung for a bronchial adenoma on 12/11/42. During the operation, she received 400 c.c. of equal parts of A and B plasma and 300 c.c. of A plasma without reaction. On the second post-operative day, five minutes after 200 c.c. of type A plasma had run in, she developed a severe chill lasting twenty minutes with an elevation of temperature from 99 to 101° F. The skin test with the plasma which gave the reaction was positive, but tests with other plasmas, both A and B and the purified A and B substances, were negative. On 12/14/42, she received 200 c.c. of type A plasma without reaction.

Case 2.—V. E., an 18-year-old male, had a right herniorrhaphy on 11/12/42. He was given 500 c.c. of type AB plasma on 11/19/42, 500 c.c. of type B on 11/20/42, 500 c.c. of equal parts of groups A and AB on 11/21/42, 500 c.c. of equal parts of groups A and B on 11/23/42. Approximately one hour after the latter plasma had been given, the patient developed a chill and a fever of 101.6° F. The fever persisted for twelve hours. Skin tests to all plasmas were negative.

Case 3.—D. W., male, aged 44, group O, had a partial colectomy on 11/4/42 and an enterolysis and enterostomy on 11/10/42. During the postoperative period following the second operation, he received 200 c.c. of type O plasma and a similar amount of the same type of O plasma on 11/20/42. On 11/21/42, approximately twenty minutes after receiving 200 c.c. of type O plasma, the patient developed a moderately severe chill and fever of 102° F. The patient was not skin tested with the reaction-producing plasma, but subsequent tests with other group O plasmas gave negative results.

Case 4.—C. G., a 62-year-old male of blood group A had a partial colon resection for carcinoma of the sigmoid colon on 12/14/42. On 12/16/42, he received 200 mg. of equal parts of A and B plasma and 400 c.c. of type A plasma without reactions. On 12/18/42 he developed severe itching and urticaria after receiving 200 c.c. type A plasma. The skin test with this plasma was positive. On 12/19/42, after receiving 200 c.c. of type A plasma, he developed a moderately severe chill and fever of 103° F. The blood pressure fell from 114/70 to 100/70 and the pulse rose from 90 to 120 per minute; the respiration rate increased from 24 to 32 per minute. The skin test to this plasma was also positive. On 12/20/42 and on 12/23/42, he received 200 c.c. of type B plasma without reactions. On each of these occasions, the skin test was negative.

It would be difficult to assign a definite cause to these reactions, but the positive skin test would be more likely to occur associated with an allergic than with a pyrogenic type of reaction. It is certain, however, that these last cases were not due to the A or B factors. We recognize the tendency on the part of clinicians to either overlook reactions or to find them "where they are not." We cite the following case to illustrate a possible false reaction and to demonstrate our awareness of the possibility.

Case 5.—C. C., 70-year-old male, group O, was acutely ill with pyonephrosis. He had daily chills and fever ranging from 100 to 103° F. On 12/10/42 while receiving 200 c.c. of type A plasma, he again developed chills and fever at 103° F. The skin test with the administered plasma was negative. This onset of the chills and fever while plasma was being given was probably coincidental with the daily chills and fever this patient had shown previously. This conclusion was strengthened, although not necessarily proved, by the negative skin test.

CONCLUSION

We have demonstrated what we consider to be important transfusion reactions due to the A and B factors in both plasma and serum. We have also observed other reactions due to factors in plasma other than the A and B substances. We have found the skin test with the plasma a good method of indicating sensitivity to the plasma in many of the cases and an aid in preventing transfusion reactions.

THE EFFECT OF SULFONAMIDE COMPOUNDS ON ANTIBODY RESPONSE TO STAPHYLOCOCCUS TOXOID*

JAMES B. WEAVER, M.D., AND MARY WHELAN TYLER, M.D., KANSAS CITY, KAN.

THIS study was undertaken to determine the effect of sulfanilamide and related compounds on the production of antibodies in response to staphylococcus toxoid injections. Only one paper on this subject was found in a review of the literature. Richou and Rastigar[1] found that there is apparently no inhibition of response in antibody development following simultaneous injections of sulfanilamide and staphylococcus anatoxin. They used two groups of five rabbits each. To one group they gave three injections of 0.5 to 3 c.c. of staphylococcus anatoxin at five-day intervals. To the second group they gave anatoxin as to Group 1 plus two intravenous injections at several hour intervals of 3 c.c. of a solution of sulfanilamide containing 1 gram in 150 c.c. saline (0.2 grain at each injection). The dose of the drug was relatively small and the length of the experimental period was short. Increasing the amount of drug given to levels comparable to that given therapeutically and continuing to administer it daily for a sufficiently long period should give a truer picture. Consequently the following plan of procedure was carried out.

White rabbits weighing between five and six pounds each were used. Staphylococcus toxoid and drug injections were begun simultaneously. Toxoid was injected subcutaneously beginning with 0.1 c.c. and increasing by 0.1 c.c. at each injection until 1 c.c. was given at a single injection. Injections were made three times a week. The soluble salts of the drugs (sulfanilamide, sulfapyridine, and sulfathiazole) were used to insure constant dosage, and as nearly as possible complete utilization. Injections were made daily throughout the life of this experiment, a period of eight to nine weeks. An attempt was made to keep the daily dose of the drugs within therapeutic limits, because we were chiefly interested in the effects produced by these drugs in the amounts usually prescribed clinically and not in the effect produced by pushing the dose to toxic levels. A control group of nine rabbits received only toxoid. Antihemolysin titers, total leucocyte counts, and hemoglobin determinations were made twice a week.

NEOPRONTOSIL

Six c.c. of neoprontosil were injected intramuscularly daily to each of seven rabbits, making an average dose of 120 mg. per kilo of body weight, which would be equivalent to 8.4 grams or 140 grains daily to a 70-kilo man. Hemoglobin levels fluctuated slightly but not more than is observed in control

*From the Hixon Laboratories of the University of Kansas School of Medicine and financed by federal funds obtained through the Kansas State Board of Health.

Received for publication, May 17, 1943.

animals living under the same conditions. Total leucocyte counts were not affected, and the antihemolysin response to toxoid injections occurred at approximately the same time after the initial injection and reached a level somewhat higher, on the average, than the controls. (Chart 1.)

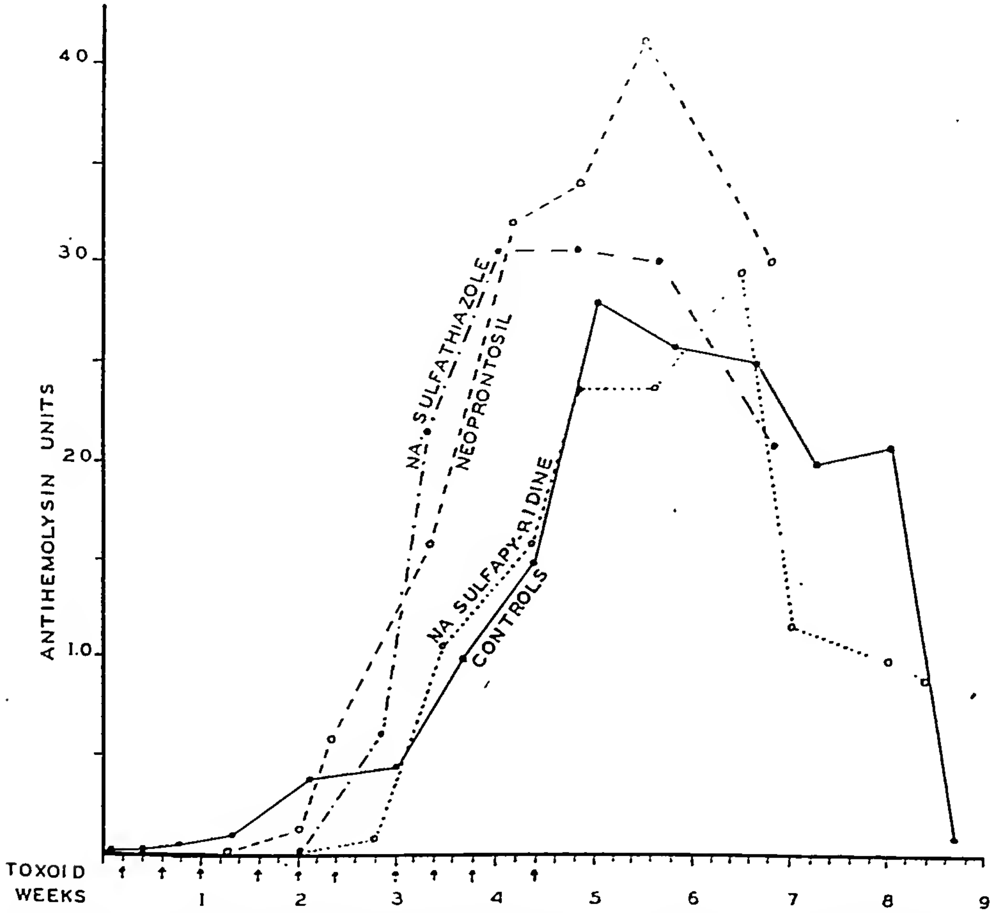

Chart 1.—Composite curves of serum antihemolysin response following staphylococcus toxoid injections in a series of control rabbits and rabbits to which neoprontosil, sodium sulfathiazole and sodium sulfapyradine were given.

SODIUM SULFATHIAZOLE*

Sodium sulfathiazole was made up in 5 per cent solution and given in the amount of 60 mg. per kilo intravenously to six rabbits. The results obtained were similar to those observed during the administration of neoprontosil. No marked fall of hemoglobin concentration was observed, and the total leucocyte count was not markedly reduced, except in two instances when counts of less than 5,000 were obtained. This, however, was only temporary, for normal counts were obtained on the following day, and no subsequent reduction was observed. Chart 1 shows that the average serum antihemolysin curve is similar to the control, except that a slightly more rapid response occurred with a slightly higher level. The concentration of the drug in the blood reached levels of from 1.3 to 5 mg. per 100 c.c.

*Kindly supplied by Dr. Newcomer of Squibbs Institute.

SODIUM SULFAPYRIDINE

A 5 per cent solution of sodium sulfapyridine was used for intravenous injections. Approximately 100 mg. per kilo were given to each of five rabbits daily. Chart 1 shows the antihemolysin curve and its similarity to the controls. The drug reached concentrations of from 1.5 to 3 mg. per 100 c.c. in the blood. Three rabbits were given an average daily injection of 250 mg. per kilo. This was done to see if doubling the therapeutic dose would affect the antibody response in any way. There was no detrimental effect, since the response to toxoid injections was as rapid and the height of the antihemolysin curve was as great as that obtained in the control rabbits. Determinations of sulfapyridine in the blood gave values of 2.5 to 9 mg. per 100 c.c. Hemoglobin concentrations and the total leucocyte counts were not affected by either dosage.

COMMENT

Sodium sulfapyridine, sodium sulfathiazole, and neoprontosil, when given to rabbits in doses which correspond to the average therapeutic dose or higher, have no effect on hemoglobin concentration, leucocyte count, or antibody response to staphylococcus toxoid injections. The antihemolysin titers became positive as soon, and in some cases sooner, in control rabbits and reached correspondingly high levels. In general, the same type of curve was obtained, the fall in titer occurring at approximately the same time after the last toxoid injection.

A NOTE ON CYSTS AND ABSCESSES INDUCED IN THE RAT BY THE INJECTION OF OILS*

FREDERICK E. EMERY, PH.D., AND CHARLES S. MATTHEWS, M.A.
BUFFALO, N. Y.

RECENTLY WE showed that peanut oil and sesame oil formed cysts when injected into the muscle of rats. Following this report,[1] several inquiries were received from persons interested in the use of oils as vehicles for hormones and other drugs. Therefore, additional experiments were performed, and in this paper we present data pertaining to the formation of cysts and abscesses following intramuscular injections of mazola, olive, cotton seed, sweet almond, sesame, and peanut oil.

METHODS

The procedure was the same for all oils and was performed by giving a single intramuscular injection of 1.0 c.c. of oil in the hind leg muscles of the rats. These rats were killed from two days to one year after the start of the experiment, and the legs were carefully examined for oil, hemorrhages, durability of cyst walls, and abscesses.

RESULTS

Mazola Oil.—The data show that this oil readily forms cysts. These cysts have firm, somewhat transparent walls and contain clear oil. They persist in the muscles for long periods of time and were found at autopsies performed as long as twelve months after the oil was injected (Fig. 1). Not one abscess has been found in more than fifty experiments with mazola oil (Table I).

TABLE I

AUTOPSY DATA TAKEN AT VARYING PERIODS OF TIME FROM A FEW DAYS TO ONE YEAR AFTER AN INTRAMUSCULAR INJECTION OF 1.0 C.C. OF OIL

NUMBER OF EXPERIMENTS	OILS	CONDITION OF OIL	CONDITION OF CYSTS			
			ABSCESSES	PER CENT	CYST WALL PRESENT	CYST WALL ABSENT
39	Mazola	Often yellow	None	--	37	2
50	Olive	Clear	None	--	48	2
46	Cotton seed	Clear or yellow	8	17.4	40	6
108	Sweet almond	Clear or necrotic	43	39.8	97	11
30	Sesame	Clear	None	--	30	None
35	Peanut	Clear	None	--	33	2

Olive Oil.—Cysts were nearly always present after intramuscular injections of olive oil. The cyst wall was thin and more easily broken than was the case with any other oils studied. Yet even these cysts may remain in the muscles for many months (Fig. 1). Oil taken from the cysts was almost always clear

*From the Department of Physiology University of Buffalo.
Received for publication, May 31, 1943.

and free from necrotic foci. Gross abscesses were not found. These facts give olive oil a high rating for intramuscular injection.

Cotton Seed Oil.—Intramuscular injections of cotton seed oil were usually followed by oil cysts. In six out of forty-six experiments cysts were not found. These negative cases are more frequent than those recorded for mazola and olive oil (Table I). The cyst walls appeared to be firmer than those formed after injection of mazola, olive, and peanut oils. Oil taken from the cysts, at intervals, during the first four months, was clear and showed no evidence of infection. The eight abscesses found (Table I) were all found in autopsies performed five to twelve months after the injections were given. Some of these were necrotic areas buoyed by the oil, while others were firm, yellow, necrotic areas from which oil could not be obtained. Since the abscesses were found only after the lapse of considerable time, it seems likely that the necrosis was not due to the irritation of the oil originally injected, but more probably developed after the oil had changed in composition and, hence, had become more irritating to the tissues. These abscesses were never found in the acute inflammatory condition as described below for sweet almond oil.

Sweet Almond Oil.—Table I shows that cysts were formed in nearly all rats injected intramuscularly with sweet almond oil. The cyst walls were well developed, semiopaque in color, and in about half of the cases so durable that the entire cyst could be removed unbroken from the muscles. In these cases the oil was usually clear. Abscesses in various stages of development were found in nearly half of the rats (Table I). These varied from spots floating in the oil to large inflammatory masses weighing as much as ten grams. When both hind legs were injected on the same day, the bilateral swelling of the legs was so severe that a few of the rats thus treated died within five days. Fig. 1 shows various sizes of the abscesses. Sometimes within a few days following the injection of sweet almond oil, the whole area of the leg was inflammatory, the oil floating in tissue fluid tinted with hemoglobin. Within a week or ten days the swelling subsided, and autopsies showed the oil largely or entirely gone and the capsule containing pus in varying amounts. Thus the picture of sweet almond oil after intramuscular injection is not gratifying.

Sesame Oil.—After intramuscular injections of sesame oil, cysts were readily formed, thus confirming previous reports.[1, 2] Additional experiments carried out during the present investigation serve as controls for the other oils, especially in regard to thickness and toughness of the capsule wall and a tendency for abscess formation. The wall developed around sesame oil is quite tough, and the entire cyst can be dissected readily from adjacent tissues without breaking. This is especially true of cysts that have been in the muscles for several months, but even in earlier stages of development the cysts formed around sesame oil are more durable than any of the other cysts studied. Abscess formation is rare, although flocculent white specks involving part or nearly all of the oil are sometimes seen.

Peanut Oil.—The injection of peanut oil intramuscularly was followed by the formation of cysts. The cyst wall is not as thick or durable as those induced by sesame oil. The oil found in the cysts is fairly abundant in amount and clear. Abscesses have not been seen in any of the rats at autopsy. This

oil seems to irritate the tissues very little and, therefore, compares favorably to mazola and olive oils; so far as we can tell, it differs from sesame oil only in the thickness and durablity of the cyst wall.

DISCUSSION

The results described make one wonder if oil should be injected intramuscularly;* certainly in rats it is obvious that sweet almond oil is very irritating to the tissues, and acute inflammation and even death may result. Cotton seed oil is less irritating, and the injected area as a rule does not become swollen; in only a few rats were abscesses formed (Table I).

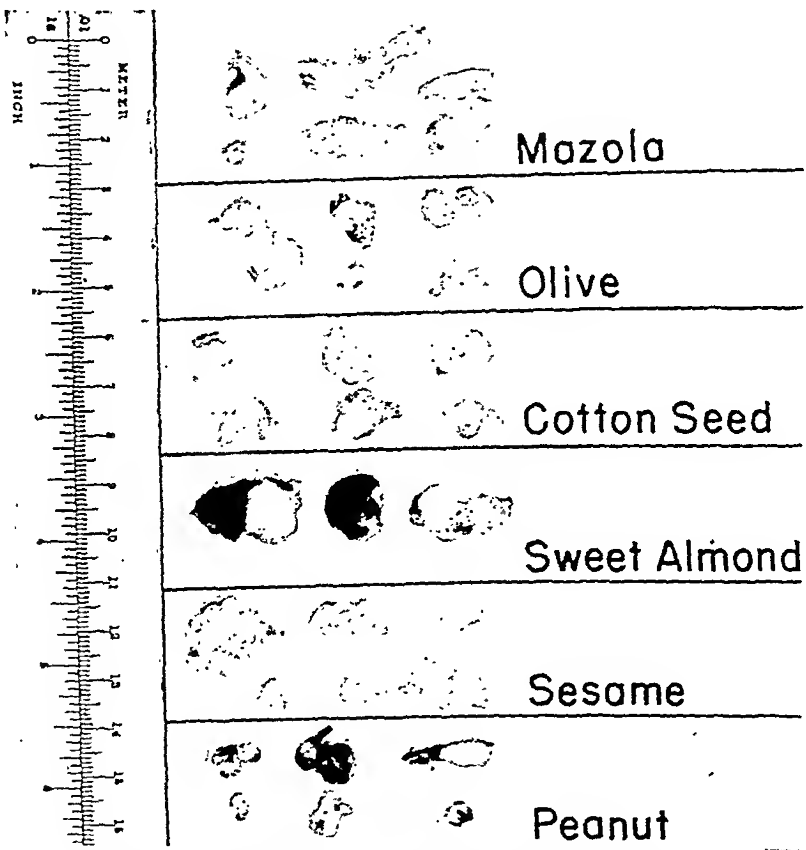

Fig. 1.—Cysts containing oil dissected from the muscles of rats after being in the muscles for varying periods up to one year.

Sesame oil induces thick and durable cystic walls which usually contain clear oil, thus confirming previous reports.[1, 2] These differences place sesame oil in preference to the sweet almond and cotton seed oil for intramuscular injections. As judged by the thickness of the capsule, mazola, olive, and

*Several letters received in regard to our first report contained inquiries concerning oil cysts in humans. Although our data are from rats, the following comments may be of value: Usually autopsy of the leg muscles is not performed. It seems likely that oil cysts would develop, but due to the small size may not be noticed by the patient. Some physicians have told us of complaints by the patient following intramuscular injections of *sesame oil*. An interne at a local hospital started to give an intramuscular injection of oil, and as a precaution he inserted the needle and aspirated. He withdrew 4 c.c. from an oil cyst formed in the muscles after previous injections. When asked what he did with the oil, he replied, "I injected it all back again."

peanut oils are less irritating than sesame oil; yet it is difficult to place one of these as first choice for intramuscular injection. In our experience all four failed to induce gross inflammatory reactions in the muscles, but like all the other oils used in this study they form oil cysts which remain in the muscles for several months.

When any one of these six oils was injected subcutaneously, the globule readily disseminated, cysts were infrequently seen at autopsy, and abscesses were never found.

Usually the injection was not carried out with antiseptic technique. Since abscesses so readily developed after the injection of sweet almond oil, careful sterilization of the oil, syringe, and needle and application of alcohol to the injected area was followed in many subsequent experiments. This careful technique had no bearing on the incidence of infection.

SUMMARY

Intramuscular injections of mazola, olive, cotton seed, sweet almond, sesame, and peanut oils were given in the hind leg of rats. A tissue capsule developed around the oil within a few days, forming an oil cyst which may remain in the muscles for at least a year. Abscesses developed in nearly half of the rats injected with sweet almond oil and in a few of those injected with cotton seed oil. Sesame oil formed a more durable cyst wall than mazola, olive, and peanut oils, but all four are less irritating than sweet almond and cotton seed oil.

ACUTE DISSECTING AORTIC ANEURYSM: TWO CASES WITH AN ANTE-MORTEM DIAGNOSIS IN ONE*

S. L. ZIMMERMAN, M.D., COLUMBIA, S. C.

DISSECTING aortic aneurysms present a varied clinical syndrome, and it is unusual for the process to present a clear-cut picture suggesting an ante-mortem diagnosis. In addition, the entity is not a common one. Flaxman[1] reports an analysis of 19 cases of dissecting aortic aneurysms which were noted in 14,160 autopsies at the Cook County Hospital between 1929 and 1941, an incidence of 0.14 per cent. In none of these cases was a definite ante-mortem diagnosis reached. He reports a similar incidence at the Charity Hospital of Louisiana, at New Orleans, and the Massachusetts General Hospital.

Up until 1933, 300 cases of dissecting aortic aneurysms were analyzed by Shennan,[2] and in addition 112 more cases have been reported. Prior to 1933 a correct ante-mortem diagnosis was made in only seven cases, and since that time the ante-mortem diagnosis has been made in 25 additional cases, bringing the total to 32 (7.9 per cent) out of 431 reported dissections.[1] In those cases in which an ante-mortem diagnosis was made there were "pointing" clinical findings, such as a sudden onset of a severe, tearing pain, usually thoracic, with variable radiation, collapse, disparity in blood pressure recordings in the two upper extremities, roentgenologic changes, etc. The main pitfall in its correct diagnosis appears to have been the confusion with coronary occlusion. The absence of a typical electrocardiographic evolution of a protracted coronary insufficiency is helpful in those cases which survive the acute dissection. Weiss,[3] however, has reported a case in which the dissection invaded the coronary artery, producing a localized area of myocardial ischemia and typical electrocardiographic changes. In those cases which may be termed "recent" the problem is more difficult. Here the entire gamut of the causes of severe thoracic pain must be differentiated, if pain be a presenting feature. It is well known on the other hand that many dissections are "silent" and are picked up at the necropsy table, much to the surprise of the clinician.

A dissecting aneurysm is a disease of later life, and it is rare before the age of fifty.[4] Flaxman,[1] however, reports one case in a youth twenty-two years of age with hypertensive heart disease.

The exact mode of its production is still a matter of conjecture. It is not definitely known whether an intimal crack or an atheromatous plaque with subsequent medial dissection presents a true picture of its genesis. The other possible mechanism advanced has been the rupture of one or more of the vasa vasorum into an already degenerated media with a subsequent formation of a hematoma. Whether or not the intimal tear results from the rupture of the

*From the Cardiological Service, U. S. Veterans Adm. Facility.
Published with the permission of the Medical Director of the Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the author.
Received for publication, June 2, 1943.

hematoma inwardly or precedes the dissection is not definitely known. The media is usually degenerated, with the production of an inelastic and brittle tube. Cyst formation, idiopathic in origin, with medial necrosis is sometimes found.

Syphilis has often been incriminated as an etiological factor. It is now known that a great many cases show no evidence of syphilis, although the two entities are by no means mutually exclusive. The role that syphilitic mesaortitis plays, in addition to a "nonspecific" medial disease, may enhance the occurrence of a dissection.[4] Hypertension, usually severe, is present in the great majority of cases. It was present in all of the 19 autopsied cases reported by Flaxman.[1] Syphilis was proved in 3, but in conjunction with hypertensive heart disease.

The mode of exitus is usually sudden and dependent upon rupture of the newly formed channel, most often into the pericardial sac, the pleural sacs, or into the peritoneal cavity. Multiple ruptures have been reported. Congestive failure, chronic but progressive, is not an uncommon termination of those cases which are protracted in their courses.

The electrocardiographic changes are often due to a coincident coronary arteriosclerosis; thus, any variety of QRS, ST-T combinations may be seen. If there is a latent coronary insufficiency, the ensuing fall in blood pressure may occasionally result in myocardial ischemia and produce electrocardiographic patterns suggestive of an occlusion. These, however, are usually slighter in degree.[5] If rupture into the pericardial sac results in cardiac tamponade, diagnostic tracings may sometimes be obtained.

The following case is reported as an additional one, unusual in the sense that an ante-mortem diagnosis was made relatively simple by the clinical course of the patient. This largely resulted because the patient was hospitalized during the time of the dissection and was observed at the probable moment of rupture into the abdomen and pericardial sac. The second case is one in which a diagnosis was not made, and it probably is typical of the usual aortic dissection in a patient who is hospitalized shortly before death. It is probable that the dissection had taken place prior to admission and that he had ruptured on the ward.

Case Reports

J. S. H., a fifty-two-year-old white male, was admitted on November 19, 1942, with a diagnosis of hypertension and arteriosclerosis. Past history was not relevant, except that there was a history of syphilis in 1916, followed by three injections of "606." Repeated subsequent serology was negative. He was a known hypertensive, asymptomatic, until four months prior to admission, at which time he noticed exertional dyspnea, progressing to the point of dyspnea at rest and orthopnea. About the same time he first became cognizant of attacks of paroxysmal nocturnal dyspnea, which increased in frequency and severity up to the time of admission. There was no history of anginal syndrome or dependant edema.

Cardiologic examination on November 24 revealed a seriously ill, dyspneic and orthopneic male, slightly cyanotic. The carotid pulsations were exaggerated. The peripheral vessels were sclerotic. Pulses were unequal, the right having a greater amplitude than the left. Blood pressure, right arm, was 220/150; left arm, 180/150. The point of maximum intensity was felt in the fifth intercostal space well outside the midclavicular line. There was some slight increase in retromanubrial dullness. The rhythm was regular. The first sound over the mitral area was of fair quality. No thrills were palpated and no murmurs were heard. Both second sounds over the bases were accentuated. On inspiration, bilateral basal râles were

heard. The liver was not felt; there was no systemic venous engorgement, and no dependent edema was present.

Visualization of the fundi revealed blurring of both discs, many hemorrhages, and hard exudates. The retinal vessels were tortuous, irregular, and fragmented. Wassermann and Kahn tests were negative. Casual urine examinations revealed a trace of albumin and occasional red blood cells. Nonprotein nitrogen was 35 mg. per 100 c.c. Electrocardiogram taken on the day following admission revealed a regular sinus rhythm, with a rate of 95. There were changes indicating left ventricular preponderance; the P-R interval varied from .13 to .16 seconds, with some changes in the configuration of the P waves in succeeding beats. QRS complexes were slurred. The T waves were inverted in 1 and 2 and upright in 3. S-T junction was slightly depressed in the first and second leads. Lead 4-F showed diphasic QRS complexes with an inverted T wave and slight elevation of the S-T junction.

Fig. 1 (Case 1).—Photograph of heart and supracardiac portion of the aorta. Note the linear rent in the supravalvular portion of the aorta. There is no separation of the commissures and no dilatation of the aortic ring. Note the tremendous hypertrophy of the left ventricular musculature. The small markings above the tear are artefacts, due to a hemostatic forceps having been applied.

Interpretation was: 1. Myocardial damage, based on inverted T waves in leads, 1, 2, and 4, depressed ST junction in leads 1 and 2, and slurring of the QRS complexes. 2. Left ventricular preponderance. 3. Wandering pacemaker. X-ray of the chest revealed an enormously increased cardiac shadow with some hypostatic congestion in both bases. The aortic shadow was reported normal. The clinical impression was: 1. Malignant arteriolonephrosclerosis, in impending uremia. 2. Hypertensive and coronary arterio-sclerotic heart disease with cardiac enlargement, myocardial damage, and left ventricular failure. 3. Hypertensive neuroretinopathy.

Clinical Course.—The course was entirely afebrile. Respirations varied between 18 and 22; pulse rate ranged between 80 and 100. The patient was digitalized on November 25, 1942, and he showed gradual improvement, so that by November 29 there was no longer evidence of left ventricular failure. At approximately 9 P.M., December 3, he was suddenly taken with severe persistent pain beginning in the region of the suprasternal notch and radiating to the lower chest, abdomen, and down the back, associated with, and followed by, a sensation of numbness in his left leg. Nausea and vomiting were both present. This pain lasted at least three hours, in spite of narcotics. At 9 A.M., December 4, he still complained of numbness in his left leg, and of nausea and vomiting. Examination at that time revealed that he had developed a loud, rough, systolic aortic murmur, which was heard throughout the entire precordium. There was a short, softer, diastolic murmur heard over the aortic area and along the left sternal border. No thrill was palpated. There was no evidence of distention of the neck veins, and the blood pressure was as follows: Right arm, 230/100;

Fig. 2 (Case 1).—Same as depicted in Fig. 1, except that the superior leaf has been elevated to better visualize the tear. See text.

left arm, 150/130. The left dorsalis pedis artery had a markedly diminished pulsation. A tentative diagnosis of acute dissecting aortic aneurysm was made. Beside roentgenogram revealed tremendous aortic and cardiac shadows, but no comparison with the teleoroentgenogram was possible, in view of the differences in technique. It must be stated, however, that the aorta appeared definitely wider than one would expect, were only such differences considered. Electrocardiogram revealed changes in the ST and T contours, the most important of which were the development of upright T waves in the fourth lead and a diphasic T wave in the second lead, as compared to previously inverted T waves. ST junctions were de-

pressed in the first and second leads, and were within normal limits in the fourth lead. The rhythm was regular, rate 150. There were no changes indicative of an acute cardiac tamponade, and there were no changes reported suggesting a diagnosis of acute coronary occlusion. At 4:30 P.M. it was difficult to feel either dorsalis pedis artery. The right posterior tibial artery pulsated normally, but the left could not be felt. He merged into rather rapid congestive failure; pulses were very unequal in amplitude; blood pressure, right arm was 260/110, and could not be obtained by the auscultatory method in the left arm; however, by palpation, the systolic pressure approximated 140 mm. of mercury. At 9 A.M. the following morning he appeared terminal and expired at 9:12. His abdomen became rigid a few minutes prior to his exitus. The final diagnosis was: 1. Malignant arteriolo-nephrosclerosis.

Fig. 3 (Case 1).—Attention is invited to the severe atheromatous changes in the entire thoracic and abdominal aorta. In the lateral view of this it can be seen that the layers have been separated by blood, but the exact point of rupture into the abdominal cavity was not found.

2. Acute dissecting aortic aneurysm, with rupture into the abdomen and pericardial sac. 3. Hypertensive and coronary arteriosclerotic heart disease. Myocardial damage, cardiac enlargement, congestive failure. 4. Hypertensive neuroretinopathy.

POST-MORTEM EXAMINATION, CASE 1

On opening the abdomen, there was a gush of fresh blood which was not clotted, estimated at approximately 750 c.c. The peritoneal surfaces showed little, if any, reaction. On opening the chest, both lungs were found to be normal in appearance. There was no fluid in the pleural sacs. Both lungs had a normal consistency. The right weighed 500 grams, and the left, 600 grams. The cut surface presented no areas of atelectasis or consolidation. The pericardial sac was tensely distended with approximately 500 c.c. of fluid and clotted blood. The serosal surfaces were smooth and glistening. The heart was strikingly enlarged and weighed 800 grams. There was a bluish discoloration of the epicardium posteriorly around the base of the aorta and pulmonary artery. A small rent, 6 mm. in length, extending through the epicardium and the adventitia of the aorta, was noted 2 cm. above the level of the aortic cusps. This could be followed into a cavity separating the adventitia and the media of the aorta.

Fig. 4 (Case 1).—Section through the lower portion of the abdominal aorta. The dark black areas depict clotted blood which has dissected between the media and the adventitia, not quite encircling the aorta.

The wall of the right ventricle was moderately hypertrophied. The bluish discoloration overlying the base of the pulmonary artery was due to a collection of blood, apparently between the media and the adventitia of the pulmonary artery from its origin to a point 3 cm. above the valve cusps. The wall of the left ventricle was markedly hypertrophied, averaging 23 mm. in thickness. The cavity was moderately dilated. The aortic valve cusps were thin and delicate. There was no fusion or widening of the commissures. The ostia of the coronary arteries were patent. The entire aorta was markedly sclerotic, stiff, and inelastic. There was a linear tear in the intima of the aorta at a level 5 mm. above the valve commissures and extending transversely across the right posterior and most of the left posterior valve. This measured 4 cm. in length. The edges were slightly ragged. This tear extended through the intima and media and opened into a complex cavity. This cavity extended, as already described, through a rent in the base of the aorta into the pericardium. It also extended the entire length of the aorta, creating a potential space between the ad-

ventitia and media which in some areas contained clotted blood. It did not completely surround the aorta, but passed about halfway around the circumference at most levels. The arteriosclerosis of the aorta was greatest in the descending portion, the intima of the ascending aorta being almost smooth. There were no tree bark wrinklings of the intima or other luetic stigmata. The exact site of perforation into the abdomen could not be ascertained, but there were no prominent ecchymoses in the periaortic fat at any point. The coronary arteries were diffusely thick-walled, and the lumen was narrowed to about ⅓ of normal. There were no areas of occlusion, however, and there was no dissection of the walls. The myocardium was red-brown and firm, and there were no areas of softening or fibrosis.

MICROSCOPIC EXAMINATION

Heart.—There was a marked hypertrophy of the muscle fibers which had large, irregular, and bizarre nuclei. In a few small areas there was a focal degeneration of occasional muscle fibers. No histologic evidence was seen of inflammatory reaction to the hemopericardium.

Aorta.—The intima was generally thickened. There were several atheromata of typical appearance, varying from the cellular phase to acellular debris with clefts where the cholesterol had been dissolved. The media was divided approximately in the middle by the dissection. In the resulting space was free blood and also adherent platelet-fibrin-leucocyte thrombi. The parallel elastic fibers of the media were intact, except for the two to three fibers immediately adjacent to the dissection where they were occasionally necrotic and often disorganized by the seepage of blood. In a few areas there was a sparse leucocytic infiltration. The line of tear was parallel to the elastic fibers. In the outer layer of the media were occasional small blood vessels and fibrotic scars, both at right angles to and parallel to the elastic lamelae. In the adventitia was a perivascular collection of small round cells, some of moderate magnitude. These inflammatory changes were not diagnostic of a syphilitic meso-aortitis.

Anatomic Diagnosis.—1. Dissecting aneurysm of the aorta with rupture into the abdomen and pericardium. 2. Marked hypertrophy of the left ventricle. 3. Arteriosclerosis of the aorta, severe. 4. Coronary arteriosclerosis. 5. Arteriosclerosis of the kidneys.

CASE NO. 2

E. W. B., a 47-year-old white male, was admitted at 4 P.M., January 13, 1943. In his left lateral chest he had had a severe attack of pain, which radiated to his substernal region on the evening of January 11, 1943. The pain was oppressive in nature and later radiated to the epigastrium; following this he became very weak and broke out into a profuse perspiration. The pain also radiated to both shoulders, but not down either arm. He vomited one and one-half hours later. At time of admission the only residual complaint was some pain in his epigastrium. He was a known hypertensive for many years, but had no complaints referable to his cardiovascular system. There was no history of rheumatic fever or syphilis.

Cardiologic examination, January 14, 1943, revealed a 47-year-old white male, propped up in bed, dyspneic and cyanotic, appearing acutely ill. There was a regular sinus tachycardia. Point of maximal intensity was in the fifth intercostal space at the midclavicular line. The apical impulse, however, was heaving and forceful and gave the impression of a markedly hypertrophied left ventricle. The sounds were booming with an accentuated A-2. There were no thrills palpated and no murmurs heard. There was no evidence of failure. Blood pressure was 240/140. The radial vessels were thickened. Electrocardiogram revealed inverted T waves in the second and third leads and the presence of left axis deviation. There was no evidence of an acute myocardial infarction.

The white blood count was 13,600, with 85 per cent polymorphonuclears and 15 per cent lymphocytes. Nonprotein nitrogen was 35. The urine was not remarkable. Wassermann and Kahn tests were negative. The temperature was 100 degrees.

A diagnosis of hypertensive and coronary arteriosclerotic heart disease, with cardiac enlargement, was made, and in spite of the elevated blood pressure, the probability of a coronary thrombosis was borne in mind. A short time following the above examination the patient expired, quietly and rapidly. Just prior to death the cardiac sounds were not discernible, and the possibility of a ruptured ventricle resulting in an acute cardiac tamponade was considered.

POST-MORTEM EXAMINATION, CASE 2

There was an extravasation of bluish red blood into the retroperitoneal tissues. This extravasation was localized, primarily, on the posterior aspect of the aorta, but also extended down along the right iliac artery almost to the pelvic outlet, around the right lateral surface of the bladder and into the base of the mesentery.

Chest.—There was no fluid nor were there adhesions in the right pleural cavity. In the left pleural cavity there were about 2000 c.c. of fresh blood containing very large fresh clots. The heart was moderately enlarged and weighed 500 Gm. There was an ecchymosis into the adventitia of the pulmonary artery which will be described subsequently. The wall of the left ventricle was markedly thickened, averaging 20 mm. The cavity was moderately dilated. The aortic valve cusps were thin and delicate but contained a few atherosclerotic plaques. There was a moderate arteriosclerosis within the sinuses of Valsalva, which resulted in a moderate fusion at the commissures of all the cusps. The ostia of the coronary arteries were widely patent. The coronary arteries were the seat of widespread and severe arteriosclerosis. There was no marked narrowing of the lumina in the first two centimeters. Beyond the first two centimeters the lumina of all major vessels were markedly narrowed at most levels to a mere pin point. The myocardium was red-brown and firm, and there were no areas of fibrosis noted. The ascending aorta and the arch were elastic, and the intima was almost free of atherosclerosis. Just beyond the opening of the left subclavian artery there was a long oblique linear rent extending through the intima and media. It was 4.5 cm. in length and occurred in a section of the aorta which was free of calcified plaques or other grossly evident abnormalities. From this point down, there was a cavity between the media and adventitia which almost completely encircled the aorta to the level of the origin of the inferior mesenteric artery. At this point, there was another transverse linear rent in the intima 1.5 cm. in length and communicating with the cavity. Below this, the dissection continued down the right side of the aorta and the right iliac artery. The left half of the aorta was not dissected at this level. Within this cavity was a large quantity of freshly clotted blood about 2 cm. in thickness at the level of the upper tear, and diminishing to a few mm. below. The intima of this portion of the aorta contained a considerable number of superficial yellow plaques, a few of which were calcified. There was no tree bark wrinkling of the intima. There was a moderate loss of elasticity of the wall. There was a marked ecchymosis into the adventitia; this was most marked in the thoracic portion of the descending aorta. It also spread upwards, though mild in degree, over the arch of the aorta, on the anterior surface of the aorta and pulmonary arteries to their bases, and into the parietal layer of the pericardium for about 6 cm. from its attachment. There was no dissection between the media and adventitia above the proximal tear. The aorta measured 6 cm. in diameter in the ascending portion and tapered down to 5.5 cm. in the descending portion. There was no constriction at any point or coarctation. The point of rupture of the adventitial tissues into the left pleural cavity could not be determined.

MICROSCOPIC EXAMINATION

Aorta.—The intima was essentially normal. The inner half of the media was composed of the usual parallel lamellae of elastic tissue. The dissection separated the outer quarter from the inner three-quarters of the media. In the space created was an adherent thrombus composed of fibrin and red blood cells with a considerable infiltration of polymorphonuclears. The inner segment of the media subjacent to the thrombus stained poorly, and the nuclei of the elastic and connective tissue fibers appeared to have dropped out. This process affected a considerable length of the media in the section taken and about one-fourth of its thickness. In the necrotic media at the base of the thrombus were many pyknotic nuclei, mostly of polymorphonuclear cells. A similar process affected most of the outer layer of the media at the level of the dissection. This necrotic process was not confined to any one segment of the aorta but was seen at several levels below the dissection. In an elastic-connective tissue stain, the elastic fibers were almost undamaged, but the intercellular substance appeared to have suffered the chief alteration. In the adventitia was a sparse round cell infiltration no more than that normally present.

Comment.—The areas of early necrosis in the aorta probably resulted from an impaired nutrition of the wall secondary to the dissection. This was suggested by their occur-

rence beneath the adherent thrombus and not to the same degree elsewhere.

Diagnoses.—1. Dissecting aneurysm of the aorta with rupture into the left pleural sac. 2. Hemothorax, left. 3. Ecchymosis into the posterior mediastinal, retroperitoneal, and pericardial tissues. 4. Arteriosclerosis of the aorta, mild. 5. Infarct, right kidney.

DISCUSSION

These two reported cases, and in addition one other case of dissecting aortic aneurysm discovered at post-mortem examination in 1936, constitute the total number of such cases observed in 31,300 admissions over a period of ten years. During this time there were 1421 deaths and 360 necropsies, giving an incidence of 0.84 per cent of the autopsied material.

The third case referred to was found in a 38-year-old white male, who had a moderate hypertension and died suddenly. The details of his clinical course are not available. Post-mortem examination revealed a tense cardiac tamponade, due to a hemopericardium. The aorta showed two transverse tears 1 cm. above the aortic ring, the edges of which were smooth, as though cut by a knife. The adventitia was separated from the media, forming a second coat which extended from the intimal tears to the diaphragmatic level, encircling the aorta for approximately three-fourths of its circumference. In the descending aorta, 15 cm. from the arch, there were three more transverse intimal tears, which were, also, smooth. There was no evidence of syphilis. Microscopic examination revealed endothelialization of the new tube, a priori evidence that the condition was not very recent. No atherosclerosis of the new aorta was present, as it was in the case recently reported by Graybiel and Sprague.[6] The heart weighed 350 grams. The coronary arteries showed advanced atherosclerotic changes.

In these three cases, hypertension of severe degree was present in two, and of moderate degree in one. The marked variation in the degree of atherosclerosis was striking, being most severe in the case illustrated, and practically absent in the second case. In the third case it was present in moderate degree.

Another interesting point was the fact that the intimal tears in all three cases occurred in a portion of the aorta which was relatively free from atherosclerotic changes. The explanation for this is obscure. The margins of these rents were straight and sharp, all conforming to the type depicted in the illustration. None of the vessels showed any of the acceptable criteria for a diagnosis of syphilitic aortitis, the serology being negative in all three, although a history of inadequately treated lues was obtained from one (Case 1). All three showed some degree of perivascular round cell infiltration in the adventitia, mild in two and moderate in the third (Case 1). There was no dilatation of the aortic ring, however, and there was no separation of the valve commissures.

While, as stated before, the presence of a syphilitic mesaortitis may enhance dissection, Klotz and Simpson[7] state that the luetic process, being a "granulomatous inflammatory process tends to weld the lamellae more closely together,"[8] so that "the wall would split less readily into its anatomic layers."

It is to be noted that the signs which may accompany this syndrome depend, in part, upon the site of the intimal tear, which usually conforms to the level of the origin of the dissection. Its subsequent course is of marked importance and varies to a considerable degree in different cases. These facts are brought out vividly when the two reported cases are compared. In Case 1, the

intimal tear occurred slightly above the aortic ring, the more usual site, resulting in the sudden appearance of a systolic and diastolic murmur. With the progression of the dissection, the likelihood of involvement of the larger vessels of the upper extremity is good, explaining the marked disparity in blood pressure readings obtained in both arms. While the blood pressure was not taken in both arms in the second case, it is doubtful, from the necropsy findings, whether any disparity had existed. Obviously, if the iliacs are involved in the dissection, differences in the pulsations of the arteries of the lower extremities may be apparent. This may or may not accompany a sensation of numbness, tingling, or coldness of the involved extremity, as was present in the first case. It was not looked for in the second case.

The striking findings in these cases were a history of severe thoracic pain, with widespread, variable radiation, the absence of electrocardiographic evidence suggesting a "protracted coronary insufficiency," and the continuation of an unusually marked, pre-existing hypertension. Both patients were obviously ill even after the pain had subsided. In the first case, the actual dissection and rupture were observed while the patient was on the ward. The additional findings of the newly developed murmurs, the disparity in blood pressure readings, and the paraesthesias and coldness of the left leg made the diagnosis relatively obvious.

SUMMARY

1. Two cases of massive dissection of the aorta are presented, in one of which an ante-mortem diagnosis was made. The pathologic description of a third case is given.

2. An idea of the incidence of this entity, and the difficulties in diagnosis are brought out. Certain factors suggesting the diagnosis are discussed.

I am indebted to Dr. Roy Barnett for the pathologic description of the heart and aorta.

THE EXPLANATION FOR THE ABSENCE OF CLOTTING IN BLOODY CEREBROSPINAL FLUID*

M. J. MADONICK, M.D.,† AND BERNARD NEWMAN, CH.E., M.S.‡
NEW YORK, N. Y.

ALTHOUGH textbooks of neurology state that the spinal fluid in cases of subarachnoid bleeding does not clot on standing and that spinal fluid admixed with blood which is produced by trauma during lumbar puncture does clot on standing, very little is reported in the literature regarding the explanation for the lack of clotting in the former.

Fresh bloody cerebrospinal fluids of fifteen patients, varying in age from 20 to 60, were studied. No clotting occurred after the lapse of many hours in any of the specimens. Slight xanthochromia was noted in the supernatant fluid of one of the specimens. Examination of the smeared sediment with Wright's stain revealed the presence of many erythrocytes, normal in size, shape, color, and staining properties, a moderate distribution of leucocytes, and what appeared to be a dearth of thrombocytes.

EXPERIMENTAL PROCEDURE

In five of the fluids selected at random, the calcium concentration varied from 4.3 to 5.1 mg. per 100 c.c. In two of the fluids, the cholesterol was either zero or a slight unreadable trace.

The cerebrospinal fluids were examined both before and after centrifuging for the presence of fibrinogen by adding to each 0.5 c.c. of fluid varying amounts of M/40 $CaCl_2$, from 0.1 to 0.5 c.c., and 0.2 c.c. of thromboplastin suspension made up according to Ziffren et al.[14] In no case did clotting of the cerebrospinal fluid occur.

It was also considered possible that an anticoagulant was present in the spinal fluid which may have accounted for the failure to clot spontaneously. Accordingly, 0.5 c.c. of the fluid was added to 2 c.c. of freshly drawn blood and permitted to stand at room temperature. In all eight of the cases in which this was done, clotting took place. The presence of such a heparin-like anticoagulating factor in the cerebrospinal fluid after nontraumatic subarachnoid hemorrhage may thus be ruled out.

In order to determine whether the amount of blood in the hemorrhagic spinal fluid would not give enough fibrinogen to permit clotting, nontraumatic spinal fluids from three normal individuals in the same age group were colored with freshly drawn blood to about the same intensity as the hemorrhagic fluids

Received for publication, June 8, 1943.

and permitted to stand. In all three of these cases, the fluids clotted in about twenty minutes to a jelly-like consistency.

In the next series of studies performed, blood plasma was added in the proportion of 0.5 c.c. to each 2 c.c. of clear centrifuged hemorrhagic spinal fluid to determine whether the criterion for clotting was the presence or absence of fibrinogen. When this was done and 0.2 c.c. of M/40 $CaCl_2$ added, the fluids clotted, but only on addition of a thromboplastin suspension. However, if to the uncentrifuged spinal fluid only plasma and $CaCl_2$ were added, omitting the thromboplastin, clotting also took place. In other words, except for fibrinogen, everything necessary for the clotting of the spinal fluid was present in the fresh hemorrhagic fluid.

The calcium determinations obtained in the fluids tested were within normal limits (Merritt and Bauer[7]). There were no alterations in the cholesterol content (Plaut and Rudy[10]). Lamb[4] emphasized the absence of clot formation in the spinal fluid of meningeal hemorrhage. He performed several experiments with fluids and blood, stating that "even though the amount of blood obtained in spontaneous meningeal hemorrhage be much greater than that required to clot a mixture of normal blood and fluid in vitro, no clotting takes place." He advanced no explanation for this phenomenon.

Our experiments indicate that the lack of clotting is due to the absence of fibrinogen. Normal spinal fluid does not contain this substance (Levinson,[5] Merritt and Fremont-Smith,[8] Strauss and Kaliski[13]). We then have to explain what happens to the fibrinogen of the blood that escapes from the source of the bleeding. We believe that there is clot formation in the cranial cavity and that the fibrinogen is thus removed. The blood that is obtained on lumbar puncture is therefore serum with red blood cells. On autopsy, performed on one of the two fatal cases in our series, clots were found in the subarachnoid spaces. Clots and hematomas in the subarachnoid spaces and even in the ventricles have been frequently described in cases of subarachnoid hemorrhage (Bagley,[1] Fearnsides,[2] Schmidt,[11] Strauss et al.[12]). The explanation for the lack of clotting is the same as that suggested by Neel[9] and by Froin.[3] The former stated that a nonartificial admixture of blood and cerebrospinal fluid "does not coagulate because coagulation has already taken place in the subarachnoid space." However, he gives no data to show how he reached this conclusion. Froin offered the explanation that in subarachnoid hemorrhage the blood forms a clot at and around the site of leaking. He further stated that the proportion of red cells comprising the clot varies according to the severity and the site of the hemorrhage. If the latter be in one of the basal cisterns where the circulation of cerebrospinal fluid is relatively unimpeded, large numbers of erythrocytes are washed off and rapidly diffuse through the subarachnoid space. If on the other hand the site of the bleeding be in the lateral ventricle, the channel of flow is relatively narrow and the great majority of red cells remain trapped in the clot. The red cells that reach the basal cistern then rapidly diffuse through the subarachnoid spaces.

We believe the mechanism is similar to the absence of clotting in menstrual blood (Lozner et al.[6]). Thromboplastin has to be added to the menstrual blood, but its addition does not seem to be necessary for clot formation in the cerebrospinal fluid.

CONCLUSION

Fresh bloody spinal fluids of fifteen patients with meningeal bleeding were examined to determine the cause of the lack of clotting. It was found that fibrinogen was absent in all cases. This, we believe, is due to the occurrence of clotting in and around the brain during which process the fibrinogen is removed from the fluid.

THROMBOPHLEBITIS MIGRANS*

Morgan Yale Swirsky, M.D., and Caesar Cassano, M.D., New York, N. Y.

THROMBOPHLEBITIS migrans is a relatively uncommon condition of unknown etiology. It involves chiefly the superficial veins of the upper and lower extremities. Widely separated regions of the body are affected with segments of normal veins between the regions of thrombosis. There is apparently no relation to pre-existing disease of or trauma to the vessels. The veins of the visceral organs are very rarely involved. Tendency to embolize is stated by many observers to be infrequent, while others stress the frequency with which it occurs in the lungs. The disease affects both sexes and all ages. The course is of variable duration and is generally benign, usually terminating in complete recovery. Approximately 100 cases have been reported in medical literature, but in only four acceptable instances has autopsy been performed.[1-4] We *disagree* with Birnberg and Hansen in accepting the case of Hirschhorn et al., because the rheumatic lesion was completely healed, was not more severe than has frequently been found in other autopsies as an incidental observation, and the acute lesion of the heart was nonrheumatic in nature. The present communication is the report of another case of thrombophlebitis migrans with autopsy. The rarity of necropsy observation seems to justify its presentation.

CASE REPORT

The patient, A. C., a 27-year-old white female, was admitted to the medical service of Dr. John Carroll, on March 7, 1942, with a chief complaint of pain and swelling of the right leg and thigh. This was of 1½ weeks' duration. For two weeks prior to the onset, she had been confined to bed with urinary frequency, urgency, burning, and nocturia. Pain which was first noted on the inner aspect of the right ankle joint soon spread up the entire lower limb as high as the groin and was accompanied by swelling of the extremity; chills, fever, and diaphoresis were absent. There was no history of trauma or any previous similar episode.

Past History.—At the age of 6 to 7 years, she had an attack of chorea without polyarthritis or apparent rheumatic heart disease. At the age of 17, shortly after the death of her mother, the patient began to gain weight and soon became very obese. Since the age of 20, she had suffered with attacks of bronchial asthma.

Physical Examination on entry revealed a very obese young white female, appearing somewhat breathless, with dark rings around her eyes. Pupils were round, regular, equal in size, and reacted well to light and accommodation. Oral hygiene was poor and the pharynx was somewhat injected. The neck was supple and no nodes were palpable. The heart was apparently not enlarged, rhythm was regular, tones were of good quality with no audible murmurs, and P_2 was greater than A_2. Blood pressure was 180 systolic and 120 diastolic. Both lung fields were full of asthmatoid wheezes and harsh breath sounds. Numerous white striae were present over the abdomen; palpation was negative. The right lower extremity showed generalized edema and local heat with exquisite tenderness to touch along the course of the saphenous vein. The left lower extremity was not remarkable. There was

*From the First Medical Division and the Pathological Laboratory, City Hospital, Welfare Island, Dept. of Hospitals.

Received for publication, June 11, 1943.

a moderate degree of clubbing of the fingers. No abnormal hirsutism was noted. Temperature was 99.3, pulse, 128, with respirations at 20.

Clinical Course.—Patient was put to bed and treated with palliative measures for three days. The fever rose slowly but steadily during this period to 103.0 accompanied by a rapid pulse rate out of proportion to the temperature, and with increasing dyspnea and cyanosis. The physical findings were suggestive of hypertensive heart disease with left ventricular failure, so-called "cardiac asthma," and a right lower lobe pneumonitis. She was treated with the usual measures with no startling results. A roentgenogram of the chest taken on the third hospital day showed diffuse irregular confluent densities throughout the right lung field, enlargement of the heart with left ventricular predominance, and hepatomegaly. The electrocardiogram revealed a simple tachycardia with a rate of 136, A-V conduction time of 0.16 seconds, slight left axis deviation, diphasic T_1, and inverted Q_3 and T_3. The blood Wassermann reaction was negative, nonprotein nitrogen, 27; sugar, 114; cholesterol, 85; cholesterol esters, 29; icteric index, 15; calcium, 9.7; phosphorus 2.56; albumin, 3.2 per cent; and globulin, 1.9 per cent. The urinalysis revealed a specific gravity of 1.022, two plus albumin, and numerous pus cells. A sputum typing was negative for pneumococci, but showed a *Staphylococcus aureus*. Despite the use of oxygen, digitalis, chemotherapy, and various supportive measures, the patient remained quite uncomfortable and ran an irregular febrile course with accompanying comparable pulse rate. The temperature ranged between 99.2 and 102.6 degrees and the pulse rate between 98 and 130 per minute. A second roentgenogram of the chest taken on the sixth hospital day showed slight clearing of the bronchopneumonic changes.

On the fourteenth hospital day, she suddenly complained of sharp and rather severe pain in the right lower chest. Examination revealed dullness to percussion with scattered moist râles over the right lower lobe, a tender liver enlarged three fingerbreadths below the costal margin, and bilateral ankle edema, more marked on the right side. The chest roentgenogram showed a consolidating process in the right lung field, while the electrocardiogram revealed depressed T_1 and T_2 but otherwise was similar to the previous tracing. Blood and urine cultures were negative although the urine continued to show numerous pus cells, albumin, and a specific gravity of 1.016. The icteric index was 18, nonprotein nitrogen, 35; cholesterol, 143; and cholesterol esters, 40. Red blood cells were 4,400,000; hemoglobin, 70 per cent (Sahli); and white blood cells, 15,000, with 83 per cent polymorphonuclears. Sedimentation time was normal. On the eighteenth day, she complained of sudden onset of severe pain in the posterior aspect of the left thigh and calf with palpatory tenderness along the course of the saphenous vein. During the following twenty-four hours, the usual findings of a thrombophlebitis appeared. She received a course of heparin ("Liquaemin") with good symptomatic relief. The irregular low-grade febrile course and accelerated pulse continued after subsidence of the thrombophlebitis, and episodes of marked dyspnea and some cyanosis continued, accompanied by scattered râles and wheezes in both lung fields and persistently elevated blood pressure of 200/126 to 250/120. The cardiac physical findings were not noteworthy.

On the forty-first day, severe pain in her left upper extremity suddenly occurred. The arm was greatly swollen, hot to touch, exquisitely tender to light palpation, and had a peculiar mottled cyanosis of the skin overlying the involved area. Another course of heparin ("Liquaemin") was given, again with dramatic symptomatic relief, and this thrombophlebitic incident apparently rapidly subsided. On the fifty-first day, she developed signs of a left upper lobe pulmonary infarction which caused her transient discomfort. On the fifty-seventh day, thrombophlebitis of the left external jugular vein developed suddenly, accompanied by severe pain and reappearance of the swelling of the left arm. A blood count the following day showed red blood cells of 3,450,000 and leucocytes of 14,300 with 85 per cent polymorphonuclears. *Staphylococcus aureus* and *Bacillus coli* were isolated from the blood. She gradually lapsed into coma, temperature and pulse rate rose steadily, and the patient expired on the sixty-first day in pulmonary edema. Final temperature was 105, pulse, 142, and respirations were 50.

Autopsy.—(Performed eighteen hours after death. Only the pertinent data are abstracted.) The body is that of a markedly obese white woman of about the stated age. There

is a two-plus pitting edema of the left arm and both legs. The right pupil is slightly larger than the left. The peritoneal cavity contains one liter of clear straw-colored fluid.

Heart.—750 grams. The pericardial sac contains 125 c.c. of a clear straw-colored fluid. The heart is enlarged in all chambers. The right auricle is covered with a thin layer of fibrin. There is abundant epicardial fat. On the anterolateral wall of the right auricle is a firmly attached friable gray thrombus covering the endocardium. The remainder of the mural endocardium is normal. The mitral valve is thickened, and along the line of closure is a row of pinhead-sized firm vegetations similar in color to the body of the cusps. On the auricular surface of the posterior cusp above the line of closure is a single larger vegetation, 1 cm. in length, firmly attached, gray-pink, and somewhat friable. The chordae tendineae are normal. The aortic, tricuspid, and pulmonic valves are normal. The left ventricle is markedly and the right ventricle moderately hypertrophied. The myocardium is of good tone and color and appears free of scar. The coronary arteries have mild to marked patches of atheromatous thickening.

Aorta.—There is an occasional atheromatous plaque in the arch and abdominal portion. The main branches are slightly dilated.

Veins.—The left jugular and innominate veins down to the junction with the superior vena cava contain firmly attached thrombi with reddish cores. Firm gray thrombi occlude the right subclavian and both femoral veins. The venae cavae, portal and hepatic veins are normal.

Lungs.—Right 975 Gm., left 550 Gm. Each pleural sac contains one liter of clear straw-colored fluid and has readily torn stringy fibrous adhesions. The posterior surface of the right lower lobe is covered with fibrin. In the right lung are many areas, irregular in size and shape, firm, granular, and friable; some are gray in color. Near the hilum is a roughly pyramidal area of the lower lobe with the base resting on the horizontal fissure. The center is gray-pink; the periphery, hemorrhagic. In both lungs, many emboli are present in the medium and smaller branches of the arteries. The tracheobronchial tree has copious quantities of seromucus, and the mucosa is mildly congested. The lymph nodes are enlarged, edematous, and blue-black.

Liver.—2,000 Gm. There is an intensification of the markings, giving it a typical nutmeg appearance. The extrahepatic biliary system is negative.

Spleen.—375 Gm. The capsule is tense, irregularly thickened, and has a few stringy fibrous adhesions to the diaphragm. The cut surface has a dark mahogany color and soft consistency. In the subcapsular zone are two small fresh infarcts, one with a gray, the other with a hemorrhagic center. The artery and vein are free of thrombosis.

Urinary System.—Right kidney, 215 Gm.; left kidney, 240 Gm. The fibrous capsules are slightly adherent, leaving a moderately coarse granular surface. The cut surfaces are edematous, but otherwise normal. The lower third of the left ureter is slightly dilated. Otherwise, the system is natural.

G. I. Tract.—There is diffuse submucosal congestion.

Brain.—1,250 Gm. The meninges are markedly engorged. Section fails to reveal any other changes. The pituitary is normal.

Paranasal Sinuses.—The sphenoidal sinus contains a light brown, moderately thick, purulent exudate which flows freely upon opening the sinus. The ethmoids, middle ears, and mastoids are normal.

Pancreas, adrenals, and generative organs are normal.

Histology.—Heart.—The left ventricle has marked hypertrophy; the right, moderate. Small perivascular and interstitial scars are present, most abundant in the interventricular wall and left papillary muscles. In a few there are small foci of lymphocytes, occasionally with mast cells. There are a few isolated foci of polymorphonuclears in the subendocardial zone of the right ventricle. Some of the intrinsic arteries have slight endothelial hyperplasia. The right coronary artery has marked atheroma and dense lymphoid foci in the adventitia. The mitral valve is thickened, fibrotic, and hyaline. It is well vascularized with thin-walled vessels and small thick-walled arteries, having a fine intimal elastification. The small vegetations are dense and fibrotic. The larger vegetation is similar and covered with a platelet thrombus.

Lungs.—There is diffuse capillary engorgement. In the right lung are foci of hemorrhage completely destroying the architectural pattern, surrounded by alveoli containing edema fluid, polymorphonuclears, and hemosiderin-bearing phagocytes. Many of the smaller arteries are occluded by well-organized, partially recanalized thrombi. It both lungs are foci of consolidation surrounding smaller bronchi.

Liver.—There is marked diffuse chronic passive congestion. The cords of the central zone show dissociation, necrobiosis, and bile pigmentation. The portal areas are not remarkable.

Spleen.—There are several small acute infarcts. The remaining portions show moderate interstitial fibrosis, engorged sinusoids, reduction of follicles, and normal central arteries.

Kidneys.—A few of the afferent arterioles have moderately thickened media.

Sphenoid Sinuses.—There is extreme destruction of the architecture of the mucosa with heavy polymorphonuclear, lymphocytic, and plasmacytic infiltration.

Left Internal Jugular Vein.—The lumen is occluded by a thrombus whose peripheral portion is organized and recanalized and has small foci of lymphocytes. The central portion has well-preserved and ghost-like red blood cells. The wall of the vein is edematous and has a mild lymphocytic infiltration.

The other organs show only extreme engorgement.

Anatomical Diagnosis.—Thrombophlebitis migrans; cardiac hypertrophy; healed rheumatic heart disease; recent and old pulmonary emboli; acute bronchopneumonia; generalized chronic passive engorgement; splenomegaly; acute infarcts of spleen; chronic sphenoiditis; obesity.

COMMENT

This case presented many of the well-recognized features of migrating thrombophlebitis and several less common findings. As has been noted frequently, the acute episodes were recurrent in nature and associated with fever. The veins involved were in widely separated regions of the body and not entirely confined to the more superficial ones. As usual, the process appeared first in the subcutaneous veins of one leg and then, by a series of relapses, involved the superficial veins of all the other extremities. Thrombosis of the deep veins, i.e., the femorals, subclavian, innominate, and left external jugular veins, occurred, associated with edema, but without gangrene. No evidence of phlebitis or thrombosis of the visceral[5, 6] or coronary veins[7-10] was noted, although the possibility of these types of involvement has been repeatedly suggested by several authors. Multiple pulmonary and splenic infarcts were present, but no evidence of thrombophlebitis or thrombosis of the pulmonary veins[11, 12] could be detected, so that the only plausible etiology must be embolism from peripheral thrombi. The clinical cardiac findings in this case coupled with those at necropsy had no fundamental relationship to the migrating thrombophlebitis.

The etiology of this disease still remains unsolved, although numerous exhaustive studies have been done on the possibilities of disturbance of clotting mechanism, focal infection, allergic types of sensitivity reaction, and fundamental relationship to Buerger's disease as primary causative factors. Many investigators have taken repeated cultures during the acute phases in the hope of proving a bacteremia or septicemia as an etiologic agent, but the results have been very disappointing. Hedblom[13] reported the presence of "nonmotile spore formers" in the blood stream in his study, and Walker,[14] the finding of *Bacillus alkaligenes*. In our case a blood culture taken early in the course of the disease showed no growth, while a culture taken forty-eight hours before death

showed *Staphylococcus aureus* and *Bacillus coli.* This may have been an agonal phenomenon, and no definite conclusions can be drawn. Unfortunately, cultures from the involved veins were not taken at the autopsy table. The rheumatic lesions found at autopsy appeared to be purely incidental findings having no relationship to the thrombophlebitis. Our conclusions were similar to those adopted in reference to the case of Hirschhorn et al.

The treatment in these cases still leaves much to be desired. Our patient received adequate heparinization, but this treatment failed to prevent further recurrences and thromboses. However, dramatic and rapid symptomatic relief was definitely obtained from the use of this agent.

THE ARTIFICIAL PHOSPHOLIPID MEMBRANE, SEMIPERMEABILITY, AND THE BLOOD-BRAIN BARRIER*

J. H. WEATHERBY, PH.D., RICHMOND, VA.

INTRODUCTION

IN A previous paper by the author (1943) it was pointed out that collodion membranes containing lecithin and cephalin exhibit some of the properties of semipermeability generally associated with membranes of living cells. Among those properties found to be common to both artificial and natural membranes may be mentioned the permeability characteristics with respect to weak acids and weak bases and the behavior of the asymmetry potential under various conditions of pH. Weak acids, such as salicylic, permeate the artificial membrane only when pH of the solution permits their existence as such and not as salts; that is to say, permeation occurs from an acid medium in which much of the acid exists as un-ionized molecules, and not from an alkaline medium in which the degree of ionization is very high. Similarly, weak bases, such as nicotine, permeate the artificial membrane only when pH of the solution permits their existence in the molecular form and not as ions; that is, permeation occurs from an alkaline medium and not from an acid one. The explanation proposed for these phenomena is based on ionization of the lecithin or cephalin molecules contained in the membrane, the nature of the ionization depending on pH of the medium in contact with the membrane. This is believed to give rise to the asymmetry potentials observed in membranes, both artificial and natural. Ions bearing charges of similar sign to that of the membrane are repelled by the membrane, and in this manner penetration of the membrane is prevented. Un-ionized molecules are not repelled in this manner, however, and penetration may occur more or less readily. A definite correlation has been found to exist between rate of penetration and concentration of un-ionized molecules of acid or base.

If the above is true, then by making relatively simple changes in molecules it should be possible to change the permeating characteristics of the molecules. For example, derivatives of nicotine in which methyl iodide is added to one or the other, or both the nitrogen atoms contained in the molecule, would be expected to ionize under all conditions of pH which do not actually destroy the molecule, and consequently should not permeate membranes containing lecithin and cephalin under such conditions. Also, the esterification of salicylic acid as in the production of methyl salicylate, or the removal of the carboxyl group to form phenol, should result in permeation of membranes by these substances under all conditions of pH which do not destroy the molecules. Some of the experiments to be described herein are offered as evidence supporting these conclusions.

In a recent review Friedemann (1942) pointed out that many substances, when introduced into the blood stream, pass from blood into brain substance, while certain others do not. The many observations by various authors referred to in this review have resulted in the postulation of the existence of a blood-brain barrier which is highly selective in its ability to permit or deny passage of substances into the brain from the blood. It is interesting to note that among substances which pass from blood to brain are the alkaloids, basic dyes, and certain toxins. Among others which do not readily permeate the brain are the acid dyes, the arsphenamines, a few toxins, and most or all the viruses. The examination of the formulas and physicochemical properties of these various substances, as far as they are known, shows that those which penetrate the brain exist at body pH, at least in part, as un-ionized molecules; whereas, those which do not penetrate exist largely in the ionic forms. Friedemann and Elkeles (1934) found that the ability of toxins to penetrate the brain is closely related to their electrical status. Those which are negatively charged do not penetrate the brain; whereas, those which are positively charged or electrically neutral at body pH do penetrate. Presumably these electrical charges may be due either to ionization of one group or another of the toxin molecule, or to adsorption of ions. An electrical charge would result in either event. The nonpermeation of viruses, as pointed out by Friedemann, may be due to the relatively large sizes of the particles; but it is interesting to note that of those for which such information is available, all are negatively charged. Certain others of the nonpermeating substances, such as trypan blue, congo red, and probably the arsphenamines, are believed to be of colloidal size, and hence do not permeate normal membranes. These facts suggest that the blood-brain barrier may be nothing more nor less than cell membranes containing phospholipids. Obviously, then, any cell membrane containing such substances would be expected to serve as such a barrier. Some of the experiments to be described are believed to have a direct bearing on this question.

EXPERIMENTAL METHODS AND RESULTS

Collodion membranes containing lecithin and cephalin (from brain) were prepared according to methods previously described (Weatherby, 1943) and were used in connection with dialysis cells such as those used previously. An effort was made to include sphingomyelin and cholesterol in some of these membranes, but was abandoned because sphingomyelin is not appreciably soluble in the ether-alcohol solvent used for collodion, and cholesterol crystallizes when the ether content of the solvent is somewhat reduced by evaporation.

Three methyl iodide derivatives of nicotine were tested, as well as nornicotine. Permeability of collodion membranes containing lecithin and cephalin to these nicotine derivatives, as well as various other substances reported either to penetrate the brain or not to penetrate it when injected intravenously, was ascertained by placing solutions of these substances on one side of the membranes and distilled water on the other. The dialysates were examined at intervals for the various substances. Generally two solutions of each substance were used, one at approximately body pH and another that was definitely acid, that is, pH 3.5 to 4.5. The results of these experiments are shown in Table 1.

An examination of this table shows that those substances which exist as salts at body pH, and are therefore subject to ionization, do not readily pass through the artificial membrane; whereas, those which exist partly or largely as un-ionized molecules at this pH do penetrate these membranes. The parallelism between penetration or nonpenetration of many of these substances into the brain from the blood stream and the permeation or nonpermeation of these same substances with respect to the artificial membrane is striking indeed. Since most, if not all, cell membranes are believed to contain phospholipids (with some, their presence has been demonstrated conclusively), it seems probable that the blood-brain barrier is one or more membranous systems, which owe their selective properties in a large measure to their phospholipid contents.

TABLE I

SUBSTANCE	pH 3.5-4.5	pH 7.3-7.4	PASSAGE OF BLOOD-BRAIN BARRIER (FRIEDEMANN, 1937)
Nicotine methyl iodide derivatives*	0	0	
Nicotine	0	+ +	
Nornicotine*	0	+	
Phenol	+ +	+ +	
Neoarsphenamine	precipitated	0	
Mapharsen	+	+ +	
Methylene blue	+	+ +	+
Toluidine blue	trace	+ +	
Methyl red†	trace	+ +	
Neutral red	0	+ +	+
Eosin	+ +	+	−
Trypan blue	0	0	−
Congo red	0	0	−

All concentrations 0.25 per cent, except as indicated.
*Molecular equivalent of 0.25 per cent nicotine.
†Saturated.

DISCUSSION

Several of the experiments reported in the table deserve discussion in greater detail. Trypan blue and congo red are colloidal, and hence could not be expected to permeate any but the most highly permeable membranes, although it is well known that the former readily passes through the damaged capillaries in an inflamed area. One would expect that neoarsphenamine, which exists as a salt in an alkaline medium, would be changed into the less highly ionizable acid form in an acid medium and that permeation of the artificial membrane would occur under these conditions. However, precipitation of neoarsphenamine (probably following decomposition) occurred within a few hours after acidification of the solution, and no permeation occurred within twenty-four hours. Methyl salicylate would be the substance to be preferred instead of phenol for comparison with salicylic acid, but this ester is not sufficiently soluble in water for such an experiment. None of the three methyl iodide derivatives of nicotine were found to permeate the artificial membrane.

With nicotine and nornicotine, just as with all other organic bases, the ratio between free base and salt at any given pH may be obtained by means of the Henderson-Hasselbalch equation, $pH = pK + \log \frac{\text{Base}}{\text{Salt}}$. The reciprocal

of this relationship holds for weak acids. The value of pK for nicotine is approximately 8.07; that is, half is free base and half salt at this pH. With nornicotine the value of pK is 9.09. At pH 7.4 approximately 18 per cent of the nicotine exists as free base, while at the same pH only about 2 per cent of nornicotine exists as such. Nornicotine permeated the artificial membrane at body pH, but much more slowly than nicotine under similar conditions. However, when pH of the nornicotine solution was increased to 9.5, the rate of permeation was greatly increased, and under these conditions it compared favorably with the rate of permeation of nicotine from a solution containing the same proportion of free base. In this connection it is interesting to note that the L.D. 50 for nicotine on intravenous injection into rabbits is approximately 6 mg. per kg., while for nornicotine it is about 3 mg. However, on intraperitoneal injection, doses of 15 mg. per kg. of nicotine killed six of ten rabbits; whereas, nornicotine in molecular equivalent doses (13.7 mg. per kg.) killed only one of ten.* Thus, nornicotine is about twice as toxic as nicotine on intravenous injection; but when passage through additional membranes is necessary before its toxic properties can be exhibited, as on intraperitoneal injection, nornicotine is much less toxic than nicotine.

It has been well established by many experiments reported by various authors that the rates of absorption of other alkaloids are dependent on pH of the media containing the alkaloids. This suggests the interesting possibility that pharmacologic activities of many alkaloids may be increased or decreased between wide limits by relatively slight changes in molecular structure so that pK is increased or decreased as interest may dictate. Or, acidic drugs such as salicylic acid and neoarsphenamine, which do not permeate membranes readily, may be made to permeate by conversion into esters or derivatives which do not form ionizable salts at body pH.

SUMMARY

1. The collodion membrane containing lecithin and cephalin is permeable to molecules, but not to ions.

2. Any factor, such as changes in pH, esterification, and salt formation, which tends to change the degree of ionization, likewise changes the rate of permeation of such membranes.

3. Those substances which penetrate the brain when injected intravenously also permeate these artificial membranes; and those which do not penetrate the brain do not permeate such membranes.

4. In view of this close parallelism it is suggested that cell membranes containing phospholipids separating blood stream and brain substance constitute the so-called blood-brain barrier.

STUDIES ON THE DETOXICATION OF ORGANIC ARSENICAL COMPOUNDS

IV. The Protective Action of P-Aminobenzoic Acid Against Lethal Doses of Neoarsphenamine Without Inhibition of Trypanocidal Potency*

J. H. Sandground, Sc.D., and C. R. Hamilton, B.S.
Indianapolis, Ind.

INTRODUCTION

FROM extensive investigations in the field of bacterial metabolism, Woods[1] offered as a stimulating hypothesis the suggestion that it was by virtue of the chemical similarity obtaining between the two compounds that p-aminobenzoic acid acts as an inhibitor of the bacteriostatic property of sulfanilamide.

The structural relationship between certain phenylarsonate derivatives, such as atoxyl, tryparsamide, carbarsone, acetarsone, etc., on the one hand and p-aminobenzoic acid (hereafter abbreviated paba) on the other, is essentially comparable to that existing between paba and many of the sulfonamide compounds. In view of this analogy, we were impressed with the possibility that the trypanocidal potentials of the afore-mentioned arsenicals might be based on a mechanism similar in principle to the bacteriostatic mechanism postulated for the sulfonamides. To investigate this possibility an experiment was set up in which a group of rats infected with *Trypanosoma equiperdum* were treated with a massive (and usually lethal) dose of carbarsone to which a substantial quantity of paba had been added. Had there been an effective diminution of the trypanocidal action of carbarsone, these rats would have died in a few days from acute trypanosomiasis. Again, on the basis of our experience, we expected that they might succumb by about the fourth day from the toxic effect of an overdose of carbarsone. Actually the majority of the animals involved in this experiment developed few and only minor stigmas of arsenical poisoning. Furthermore they successfully overcame the hazard of death from trypanosomiasis.[2]

More interesting to us at the time than the failure of paba to inhibit the trypanocidal action of carbarsone was the entirely unsuspected possession by paba of a capacity to neutralize the lethal property of massive doses of carbarsone. This deduction was amply confirmed by further work not only with carbarsone, but also with such analogous pentavalent arsenicals as phenylarsonic acid, arsanilic acid, acetarsone, etc.[3] Later it was found that paba also has the capacity to protect rats against the lethal action of pentavalent phenyl stibonates, as exemplified by the German proprietory drug, stibosan.[4]

With a view to elucidating the mechanism underlying detoxication by paba, a large series of experiments were carried out. It was found[5] that a single administration of paba at the rate of 500 mg. per kilogram body weight can

*From the Lilly Research Laboratories.

Received for publication, July 8, 1943.

protect the lives of rats against several pentavalent arsenicals in quantities which considerably exceed their so-called "universal lethal dose" or $L.D._{100}$, e.g., 1500 mg. per kilogram of carbarsone, 450 mg. per kilogram of arsanilic acid, etc.

Of special interest and possibly of theoretical significance in connection with the mechanism of the detoxicating action was the finding that, whereas maximum beneficial effect is achieved when paba is injected simultaneously with, or even some time *prior to* the arsenical, when paba is introduced *subsequent to* the arsenical, its value is reduced almost in direct proportion to the interval that elapses.[6]

Unfettered by any theory as to the biochemical mechanism of the detoxicating process, our attention was directed early in the course of these investigations to determining broadly the potentialities and limitations of paba in conjunction with an array of other arsenical and antimonial compounds. Numerous experiments have been carried out with inorganic and organic arsenicals as represented by sodium arsenite, sodium cacodylate, mapharsen, arsphenamine, and neoarsphenamine, and the organic trivalent antimonial, tartar emetic. While paba was always used in substantial quantities as a detoxicant with the above-mentioned toxic substances, only in conjunction with neoarsphenamine were we able to obtain what seems to be unequivocal evidence of its capacity to interfere substantially with the lethal effect of large doses of the drug.

In view of the importance of neoarsphenamine in the treatment of syphilis, it is hoped that the publication of our experimental findings in this journal may be of interest.

EXPERIMENTAL PROCEDURE

Technically much greater difficulty is encountered in demonstrating clearcut detoxication of neoarsphenamine than is to be experienced in proving detoxication against such drugs as carbarsone. This difficulty arises from the fact that, in contrast with the chemical purity of the pentavalent arsenicals and the crystalloidal nature of their aqueous solutions, the trivalent arsenobenzene compounds, such as arsphenamine and neoarsphenamine, are physicochemical complexes which are difficult to prepare in the state of purity indicated by their theoretical formulas. The toxicity rating and therapeutic efficacy of different lots of these compounds can only be established by biological assays. Because of the variation inherent in individual animals, this procedure, besides being expensive in terms of time, involves large numbers of animals, standardized so far as feasible by breeding, sex, age, and weight. The results of assays usually require the application of statistical methods for their correct interpretation.[7] However, even when tests with a homogeneous population of rats are performed with exacting attention to detail (e.g., in special air-conditioned rooms), nebulous and uncontrollable meteorologic factors seem to influence the mortality rates.[8] At best, the results obtained from such toxicity assays are to be interpreted as relative (to a standard) and can validly be presented only in terms of the median lethal dose ($L.D._{50}$).[9, 10]

The demonstration of the possession by any substance of a detoxicating action against neoarsphenamine must necessarily involve the same principles of

procedure, unless the detoxicating action is of such a high order that notwithstanding adverse conditions attending the assays, the results of protection tests are so obvious that statistical "booby traps" do not represent a hazard to their interpretation.

Largely as a consequence of prevailing conditions of supply as well as of other fortuitous circumstances, the experiments the results of which are recorded below were conducted with rats of a very heterogeneous assortment obtained through several animal dealers. Three lots of neoarsphenamine were used, each of a different manufacturer's brand purchased on the open market. On testing, one of these lots, "C," turned out to have a much higher toxicity for rats than did the other two. After preliminary toxicity tests with the particular lot of arsenical, protection experiments involving from 5 to 20 rats with an approximately equal number of unprotected controls were usually set up on one or two dosage rates. The assays were often repeated at the same dose rate or, if need be, with higher or lower doses of neoarsphenamine.

Despite the several handicaps to uniformity of results, it has been our experience that the outcome of a protection experiment was not essentially different, whether the assay was performed with the conventional young male 100-gram rats, of highly inbred strain and starved the night before testing, or whether we utilized the more readily available "mongrel" rats weighing up to 175 grams. The only precaution we have observed was to see that the drug was administered in quantities proportional to the rat's weight and to match rats of various weights equally between "treated" and "control" groups.

Obviously in order to secure meaningful data with a limited number of rats, it is necessary that the outcome of a protection experiment should show a significantly higher mortality rate in the control series than in the protected group. This calls for a rather nicely adjusted neoarsphenamine dosage approaching the maximum tolerance level. To go appreciably beyond this point, as we have on several occasions learned to our consternation, may lead to the death of all or nearly all of the animals, both "protected" and "controls." Another difficulty that can arise is characterized by the death of a large proportion of rats within a very few hours or even minutes of injection. This may happen irrespective of the dosage of arsenical and any protective treatment that may have been attempted. Agonal symptoms in such cases are referable to an acute vascular disturbance. Deaths of this order are clearly distinguishable from the normal, truly toxicologic fatalities that develop in from one to three or more days following injection. Wright et al.[11] found that the colloidal (in contradiction to crystalloidal) fraction of solutions of neoarsphenamine was responsible for the so-called immediate toxic reactions in 85 per cent of their rats that suffered precipitate deaths from respiratory failure. In some respects deaths of this type (which are, apparently, beyond the protective control of paba) resemble the "nitritoid crisis" or acute vasoparetic reaction, an ever present element of risk in the arsenic treatment of syphilis. Rather late in the course of our investigations we found that the incidence of deaths of the immediate type with the resultant waste of material and effort could be considerably reduced by employing subcutaneous injection in lieu of the usual intravenous (caudal or saphenous vein) route of introducing the drug.

The freshly prepared aqueous solution in 2 to 5 per cent concentration is

injected either simultaneously with, or not more than fifteen minutes after, the administration of a fresh 10 per cent aqueous solution of the sodium salt of p-aminobenzoic acid. Our rats have been accommodated in large communal cages, provided with ordinary commercial "chow," and kept under observation for at least ten full days before termination of the test.

TABLE I

COLLATED RESULTS OF EXPERIMENTS

PROTECTIVE ACTION OF p-AMINOBENZOIC ACID ON RATS RECEIVING MASSIVE DOSES OF NEOARSPHENAMINE

NEOARSPHENAMINE BRAND	NEOARSPHENAMINE DOSE MG./KG.	DOSE OF PABA MG./KG.	PABA-TREATED RATS NO. USED	PABA-TREATED RATS NO. SURVIVED	NONPROTECTED CONTROLS NO. USED	NONPROTECTED CONTROLS NO. SURVIVED

	215 subcutaneously	1000 intraperitoneally	20	12	20	0

DISCUSSION

That paba possesses in substantial measure the power of protecting rats against the lethal effect of high doses of neoarsphenamine is, we believe, conclusively demonstrated from the results of experiments tabulated above, even without resorting to mathematical treatment of the figures to fortify this inference. Had we summarily eliminated from consideration those animals that died shortly after injection (as is sometimes done[10] in official assays of neoarsphenamine toxicity), the resulting figures would have supported the contention with even greater force. While "death" as the end point of a biologic reaction is by its very finality the most rigid measure that can be employed for the demonstration of protection (or the absence of protection) against a potent poison, the "all or none" nature of the criteria used in expressing the results of an experiment does not permit the introduction of fractional values into the situation. Such "fractional values" as are brought out by comparing the survival time of all rats in treated and control groups, or by contrasting their general condition and toxic reactions, are by no means insignificant. This is well illustrated by the accompanying photograph of three rats taken on the final day of the experiment, the tenth day after treatment with 175 mg. per kg. neoarsphenamine "Brand C." The normal-looking animals, 1 and 3, have received paba and are typical representatives of the protected survivors. Rat 2 is the only animal living out of 10 controls. It has lost weight (from 100 grams to 58 grams), and for several days appeared moribund. The fact that this animal escaped death, even though by a narrow margin, leads to its survival being credited in the protocol of results with the same unit value as any one of the paba-treated rats, e.g., 1 and 3, which have grown from 100 grams to 138 and

141 grams respectively without ever having been greatly indisposed by their arsenical medication. It is interesting to note in this connection that in our series of experiments the protective capacity of paba received its most rigorous test and appears to be most unequivocally demonstrated when a batch of neoarsphenamine (Brand C) of higher than usual toxicity was employed.

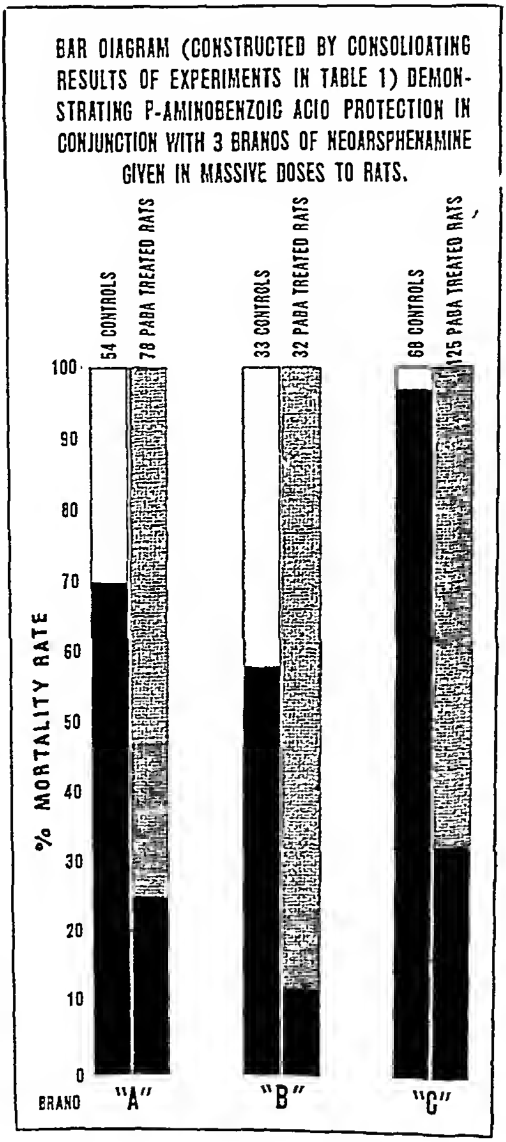

Fig. 1.

The clinical implication of the discovery that in rats paba has definite detoxicating value in conjunction with neoarsphenamine is difficult to evaluate without a critical trial. The subject is of sufficient importance to warrant a more extended consideration of its theoretical aspects than present space will permit. If paba is found to exercise a protective influence in human medication with neoarsphenamine, the question of its possible interference with the latter's treponemicidal activity will determine its clinical usefulness. In this connection,

the fact that in numerous experiments performed by us with *Trypanosoma equiperdum* paba in relatively large quantities was not found to diminish the parasiticidal value of neoarsphenamine may be of inferential significance.* This is to be contrasted with the experience of Durel,[13] who found that while solution of novarsenobenzol (=neoarsphenamine) in ascorbic acid appeared to reduce the toxicity of the arsenical in mice, the death rate from *Trypanosoma brucei* following treatment with a uniform dose of novarsenobillon was directly proportional to the amount of ascorbic acid contained in the mixture.† Loss of therapeutic efficacy with high doses of vitamin C in conjunction with arsenotherapy has also been suggested in clinical observations by Cormia.[14]

Fig. 2.—Photograph of rats treated with 175 mg. per kg. neoarsphenamine. Rat 2 is the sole survivor of 8 controls (see text). Rats 1 and 3 are typical of the 16 survivors out of 20 animals that received a simultaneous injection of *p*-aminobenzoic acid.

It should not be necessary to remark that a great chasm separates experience acquired with animals in the experimental laboratory from that which may be experienced in the clinic. Differences in the results obtained sometimes reflect fundamental differences in the metabolic processes of the animal species as reflected in their methods of disposing of certain chemical substances, e.g., benzoic acid. Frequently, however, the differences may be ascribed to the lack of parallelism between the conditions governing the laboratory experiment and those which are feasible when dealing with human lives. In advance it may be well to remark that in rat experiments the evidence of "paba" detoxication is best brought out by using doses of neoarsphenamine of a magnitude that has no parallel in the clinic unless it be in conjunction with the intensive arsenotherapy of syphilis. No evidence has been disclosed that would warrant the assumption that paba can act as an effective antidote against a toxic condition induced by the *prior* administration of arsenicals or that the concomitant administration of paba will eliminate the danger of the "nitritoid crisis" or counteract an "acquired sensitiveness" to arsenicals.

SUMMARY

Proceeding from a knowledge of the capacity of p-aminobenzoic acid to protect rats against the "certain lethal dose" ($L.D._{100+}$) of various pentavalent

*This inference is strengthened by the incidental observation of Osgood[12] who succinctly remarks "p-aminobenzoic acid does not interfere with the action of neoarsphenamine as it does with the action of the drugs of the sulfanilamide group."

†Incidentally, it may be recorded that in several parallel experiments we have not found ascorbic acid to have detoxicating power comparable with that of paba.

arsenical and antimonial compounds, a large series of experiments have been performed to determine the scope of paba protection in conjunction with several trivalent arsenical and antimonial drugs.

It appears that paba has no detoxicating capacity against inorganic arsenous acid; the arsenoxide mapharsen; the arsenobenzene arsphenamine; or the trivalent organic antimonial tartar emetic.

Against neoarsphenamine, protection experiments with a large series of unselected rats are reported in this paper. The results show a very substantial reduction in the mortality rate without a concomitant inhibition of its parasiticidal potency as measured by its effect on trypanosomiasis in the rat.

The clinical implication of these findings, especially in connection with the intensive treatment of syphilis, warrant further investigation.

CLINICAL CHEMISTRY

ABSORPTION, EXCRETION, AND DISTRIBUTION OF SULFAMETHAZINE (2-SULFANILAMIDO-4-6-DIMETHYL-PYRIMIDINE) IN MAN*

JOHN K. CLARK, M.D., FRANKLIN D. MURPHY, M.D., AND
HARRISON F. FLIPPIN, M.D., PHILADELPHIA, PA.

THERE has been a marked improvement in the therapeutic efficacy and lack of toxicity in the series of sulfonamides that has been introduced for clinical use since sulfanilamide. Among the more recent of these compounds, sulfamerazine (2-sulfanilamido-4-methyl-pyrimidine) and sulfamethazine (2- sulfanilamido-4-6-dimethyl-pyrimidine) have warranted clinical trial because of their therapeutic effectiveness against various experimental infections and the relatively high solubility of their acetylated forms.

Since the intelligent use of these drugs requires an understanding of their behavior when administered to man, we have investigated their fate in a group of patients. In a recent paper,[1] we reviewed the experimental data pertaining to sulfamerazine and presented observations dealing with its behavior in man; this suggested that sulfamerazine is pharmacologically satisfactory. At this time we are reporting the results of a similar study on sulfamethazine† and have made a comparison of the two drugs on the basis of their absorption, excretion, and distribution in human beings.

Sulfamethazine (2-sulfanilamido, 4-6-dimethyl-pyrimidine), described by several groups of investigators,[2-4] is a dimethyl homologue of sulfadiazine. The therapeutic effectiveness of sulfamethazine against experimental infection has been investigated by Rose, Martin, and Bevan[4] and found to be highly active against pneumococcal and streptococcal infections in mice. Pharmacologic studies, both in mice and human beings,[4] indicate that the drug is freely and rapidly absorbed from the gastrointestinal tract and it is stated to be slowly eliminated from the blood stream. Furthermore, it was suggested that, because of its high solubility, sulfamethazine is unlikely to cause renal damage.[4] Preliminary clinical trials with the compound have shown that it is highly effective in pneumococcal, meningococcal, and gonococcal infections and is less toxic than is sulfapyridine.[5, 6]

The methods used in this investigation were the same as those employed in the sulfamerazine study.[1]

*From the Department of Medicine and the William Pepper Laboratory of the Hospital of the University of Pennsylvania.

This work was aided by a grant from the Sharp and Dohme Laboratories, Glenolden, Pa.
Received for publication, July 13, 1943.

†The sulfamethazine used in this study was supplied us by Sharp and Dohme Laboratories, Glenolden, Pa.

RESULTS

A. Absorption.—

1. *Single Oral Dose.*—Nine patients (Nos. 1 to 9, Table I) were given a single 3 Gm. dose of the drug. At the end of 2 hours the average concentration of free sulfamethazine in the serum was 11.1 mg. per 100 c.c., and, after 4 hours, the average concentration reached a peak of 12.0 mg. per 100 c.c. Thereafter, the level began to fall, and at the end of 12 and 24 hours it averaged 6.1 and 2.2 mg. per 100 c.c. respectively. Acetylation of the drug varied. At the end of 6 hours an average of 21.6 per cent of the total drug was in the acetylated form; at 12 hours, 37.1 per cent, and after 24 hours, 48.8 per cent.

2. *Single Intravenous Dose.*—Two patients (Nos. 10 and 11, Table I) were each given 3 Gm. of sulfamethazine sodium in 5 per cent solution in sterile distilled water intravenously. Within one-half hour the average level of free drug was 15.3 mg. per 100 c.c.; in 2 hours the concentration averaged 11.4 mg.; after 4 hours, 9.5 mg.; and, at the end of 24 hours, 1.9 mg. per 100 c.c.

3. *Single Subcutaneous Dose.*—Two patients (Nos. 12 and 13, Table I) were each given 3 Gm. of sulfamethazine sodium, 0.5 per cent concentration in 0.85 per cent sodium chloride solution, subcutaneously. The average concentration of free drug reached a peak of 8.5 mg. per 100 c.c. at 2 hours, within 4 hours the level was 7.1 mg., after 6 hours, 5.9 mg., and at the end of 24 hours, 0.5 mg. per 100 c.c. Acetylation of the drug after parenteral administration very closely paralleled that found with oral administration.

4. *Multiple Dosage.*—Twelve patients, suffering from several diseases, including pneumococcal pneumonia, meningococcal septicemia, puerperal sepsis, postoperative pneumonia, were treated with sulfamethazine for varying periods of time and with different dosage schedules. In general, they were given 2 to 4 Gm. by mouth, followed by 1 Gm. every 4 to 6 hours. Serum levels varied widely from 1.0 to 23.0 mg. per 100 c.c. of the free drug with an average acetylation of 38.3 per cent (range 0.8 to 83.5 per cent). While serum concentrations of sulfamethazine varied greatly from person to person, they were constant for the same individual.

B. Excretion.—

Urinary excretion of the drug was measured (Table I). After the oral administration of a single 3 Gm. dose, from 17.1 to 55 per cent (average 40.1 per cent) was recovered in the first 12 hours; by the end of 24 hours from 40.8 to 90 per cent (average 71.8 per cent) had been excreted, and, at the end of 48 hours from 67.6 to 98.8 per cent (average 86.2 per cent) of the ingested drug was recovered from the urine. During the first 24 hours an average of 70.9 per cent of the excreted drug was in the acetylated form, and, after 48 hours, 77.3 per cent was acetylated drug. Similar results were obtained when the drug was given parenterally (Table I).

C. Distribution.—

1. *Cerebrospinal Fluid.*—Four patients (Nos. 14, 15, 16, and 17, Table II) were given the drug by mouth, and cerebrospinal fluid and blood specimens were obtained at varying intervals. Six hours after the administration of 3 Gm. of sulfamethazine, the ratio of the cerebrospinal fluid level of free drug to that

in the serum was 0.04 (No. 14). After 12 hours, following a similar dose of the drug, the ratio was 0.58 (No. 15). Two patients were given multiple doses of sulfamethazine, and after 24 hours (No. 16) and 11 days (No. 17) the ratios were 0.33 and 0.29 respectively.

2. *Pleural and Ascitic Fluid.*—In three patients (Nos. 18, 19, and 20, Table II) who received sulfamethazine pleural or ascitic fluid and blood samples were taken at varying intervals. Ratios of 0.86 and 0.53 were obtained in pleural fluid 12 hours (No. 18) and 4 days (No. 19) following 3 and 20 Gm. of the drug respectively. In one patient (No. 20), after 20 Gm. of the drug, the ratio of 0.51 in ascitic fluid was obtained.

3. *Erythrocytes.*—Simultaneous determinations of sulfamethazine concentration in serum and whole blood were performed in a single patient (Table III). The results in this instance show that the drug penetrates the red blood cells.

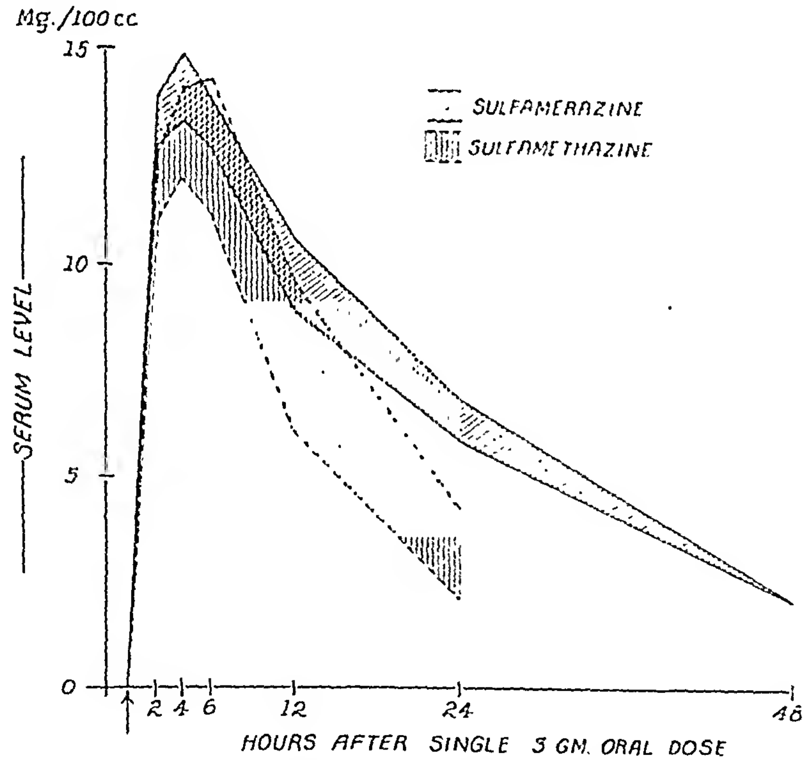

Fig. 1.—Comparison of average serum concentrations obtained in 9 subjects receiving 3 Gm. of sulfamethazine with those obtained in 8 subjects receiving a similar amount of sulfamerazine. In each curve the lower line indicates free drug and the upper line, total drug.

DISCUSSION

Comparison of these data on sulfamethazine with recent studies in this laboratory on sulfamerazine[1] indicates that the two drugs are absorbed from the gastrointestinal tract with equal rapidity (Fig. 1). The rate of excretion of both free and acetyl-sulfamethazine is greater than that found with sulfamerazine and its acetyl derivative (Fig. 2). The two drugs diffuse readily into various body tissues and tissue fluids. In view of the greater solubility of

sulfamethazine,[3] the incidence of urinary complications may be less than with sulfamerazine. Because of its rapid excretion and high acetylation, both in serum and urine, sulfamethazine appears to be less satisfactory from a pharmacologic viewpoint than sulfamerazine. The above findings are in keeping with those recently reported by Welch and his associates.[5]

SUMMARY

Data are presented concerning the absorption, excretion, and distribution of sulfamethazine in humans. They show: (1) that sulfamethazine is readily absorbed from the gastrointestinal tract; (2) that it is rapidly excreted in the urine; and (3) it readily diffuses into pleural, ascitic, and cerebrospinal fluids and into the red blood cells. Comparison with the behavior of sulfamerazine shows that higher blood concentrations are sustained longer with sulfamerazine than after similar amounts of sulfamethazine.

STUDIES IN THE PHARMACOLOGY OF MERCURY

III. Histochemical Demonstration and Differentiation of Metallic Mercury, Mercurous Mercury, and Mercuric Mercury*

W. C. Hand, B.S., B. B. Edwards, B.S., and E. R. Caley, Ph.D.†
New Brunswick, N. J.

Mercury and its compounds have been used for many years in the prevention and treatment of syphilis; yet a review of the literature discloses little material on methods for observing the valency changes which may take place during and after the absorption of mercury and its derivatives from the skin and other depots of administration. The development and utilization of differential methods for demonstrating mercury in the organs of the body should serve to extend our knowledge of the pharmacology of this element and perhaps lead ultimately to more efficacious clinical preparations. In this paper we present some new histochemical methods together with a review and extension of certain older ones.

CHEMICAL CONSIDERATIONS

General.—It is self-evident that a histochemical reagent should react in a characteristic manner with the substance to be detected. As Christeller[1] points out, this is easy in the case of iron, since there are a number of brilliant-hued specific chemical reactions. In spot tests[2] mercury likewise gives fairly specific color reactions with such reagents as diphenylcarbazide and dithizone. Our experiments with the above reagents on sections known to contain mercury compounds were disappointing. The color was either too faint or too evanescent. Precipitation with sulfides according to the procedures of Justus[3] and of Almkvist[4] also gave inconclusive results. The particle size of mercury sulfides formed in tissues may be extremely small, so that it is difficult to differentiate them from hemosiderin and other pigments. The use of iodine and iodide proved fruitless, as previously noted by Christeller because the entire section is stained. We ultimately confirmed the conclusion previously reached by Lombardo[5] and by Christeller that the reduction of mercury in the tissues to the metallic form is the simplest and most reliable histochemical procedure.

Metallic Mercury.—As has been pointed out by Zwick[6] and by Emich,[7] the microscopic appearance of finely divided mercury is highly characteristic. The particles are spherical, black, and nonrefractile. When sufficiently large, an image of the lens of the objective is reflected from their centers. Their very roundness makes them subject to ready displacement, however, and the section is best cut rather thick (15 microns) if free mercury is suspected, in order that a comparatively undisturbed inner zone may be available for inspection.

Zwick demonstrated that metallic mercury is present in the subcutaneous

tissues after innuction of the element in a salve vehicle. We have confirmed this observation. He pointed out that the globules react with components of tissue fluids and lose their spherical shape. According to Christeller, they dissolve completely in tincture of iodine and this characteristic reaction may be observed under the microscope. We have observed further that solutions of chlorauric acid react with the minute spheres, causing at first a loss of gloss and a roughening of surface; this is followed by a gradual disintegration of the spheres as the gold amalgam forms. These changes were observed microscopically in sections of tissue. The above-mentioned characteristic microscopic appearance and microchemical behavior permit positive identification of the metal.

Mercurous Mercury.—Compounds containing mercurous mercury are usually colorless. Most mercurous salts, for example, the acetate, combine or mix with blood and other protein systems without the formation of opaque or colored bodies. For histochemical purposes, it is accordingly necessary to render the compounds visible. This can be done, even in the presence of mercuric mercury, by employing a reagent with a selective reducing action, so that only the mercurous mercury is reduced to the metal. Thioglycollic acid exhibits this differential selective reducing effect. In test tube experiments calomel is reduced immediately. Under the microscope, a suspension of calomel crystals is transformed almost instantaneously to a dispersion of metallic globules, when a drop of thioglycollic acid is introduced under the cover slip.

Mercuric salts are not so reduced. They react with thioglycollic acid to form compounds which appear as colorless to yellow crystals. We have not attempted to determine the precise nature of these compounds as they are found in histochemical reactions. It has been reported, however, by Claesson[8] that mercuric compounds react with thioglycollic acid to form either mercurithioglycollic acid ($Hg[S.CH_2COOH]_2$) or mercuric thioglycollate ($Hg[S.CH_2COO]_2Hg$), according to conditions. It is likely, that in the histochemical testing where an excess of reagent is normally present only the first of these two compounds is formed in appreciable amount. The presence of crystals of mercurithioglycollic acid does not interfere with the histochemical interpretation of the sections. Although the appearance of the crystals is rather characteristic, we do not recommend that they be regarded as an index of the mercuric mercury present. This reservation is based on the fact that they may dissolve and recrystallize at a point remote from the original site of the mercuric compound.

Tissue sections which contain mercurous mercury exhibit a prompt formation of mercury when a thioglycollic acid solution is introduced under the cover slip. The gradual formation of these globules can be followed visually. Should mercuric mercury also be present in appreciable amount, characteristic yellowish crystals begin to form after about five minutes.

Mercuric Mercury.—It was established by Lombardo and confirmed by Christeller that mercury is precipitated from tissues by stannous chloride solutions. This is a well-known chemical phenomenon which can be demonstrated readily in the test tube. Stannous chloride solutions reduce both mercurous and mercuric salts (including the thioglycollic acid mercury salts) to free mercury. It is thus possible, first, to examine a section for free mercury, then, to detect the mercurous mercury with thioglycollic acid, and, finally, to

detect the remaining mercuric mercury with stannous chloride. In actual practice, however, we prefer to treat three separate serial sections with the several reagents as described below. Sodium stannite solutions also are effective, but they macerate the tissue.

SUITABLE REAGENTS

General.—The reagents used in these studies were developed by a process of trial and error. It is not claimed, nor maintained, that they represent the best possible embodiment of the reducing agents. They have been tested, however, on thousands of sections from more than fifty animals including rabbits, guinea pigs and mice, with satisfactory results. In general, no counterstains have been employed. In our experience counterstains tend to displace the mercury globules.

Metallic Mercury.—As has been noted elsewhere, it is not necessary to use a reagent to demonstrate the presence of free mercury. Inasmuch as this work has been done almost exclusively with frozen sections, however, a clearing agent is employed. Its formula is as follows:

Formula I:	Tartaric acid	5 Gm.
	Glycerin	100 milliliters
Preparation:	Add the acid to the glycerin and agitate. The crystals will dissolve overnight.	

The above solution removes hemosiderin deposits and provides sections which exhibit adequate cellular detail without counterstaining.

As a confirmatory test to dissolve the mercury, official tincture of iodine may be used.

Formula II:	Iodine	70 Gm.
	Potassium Iodide	50 Gm.
	Distilled Water	50 Gm.
	Ethyl Alcohol, 95 per cent	To make 1000 milliliters
Preparation:	Dissolve potassium iodide in the water, add the iodine and agitate until solution is effected. Then add sufficient alcohol to make 1000 milliliters and mix thoroughly.	

The gold amalgam reaction is sometimes useful in fresh frozen sections of the skin because it does not stain initially as intensely as does iodine. This test is occasionally useful when confusion is experienced with skin pigments.

Formula III:	Chlorauric acid	1 gram
	Distilled water	99 milliliters
Preparation:	Dissolve the chlorauric acid in the distilled water in the cold with stirring. This reagent should be stored in a dark bottle.	

Mercurous Mercury.—The following solution of thioglycollic acid has been found satisfactory:

Formula IV:	Thioglycollic acid	1 milliliter
	Glycerin	9 milliliters
Preparation:	The above are completely miscible.	

Mercuric Mercury.—Stannous chloride reagent of the following composition may be stabilized by adding a few grams of metallic tin to the final solution which should be kept in a well-stoppered bottle.

Formula V:	Stannous chloride	5 Gm.
	Tartaric acid	5 Gm.
	Glycerin	100 milliliters
Preparation:	Combine and heat until the solution is clear.	

HISTOLOGIC TECHNIQUE

Throughout this study, every attempt was made to avoid artefactual changes in the tissues. The extended fixation of tissue advocated by Christeller and Lombardo may result, as the former author noted, in a *leaching out* of mercury compounds. Also, the immersion of whole sections permits diffusion of mercury compounds within the specimen with the resultant introduction of unpredictable inaccuracies in the final readings. Furthermore, the usual histologic fixations may similarly contribute an unknown artefactual change in the specimens. As a matter of fact, Christeller observed that formalin and alcohol decreased his yield. In work with frozen sections of material previously fixed in alcohol or formalin, we noted, histochemically, that our reagents usually produced a precipitate on the exposed surface of the sections only. For these reasons and in the interests of more rapid work, unfixed frozen sections were employed in our experiments.

In our standard practice the sections are taken immediately after sacrificing the animals, because experience showed a loss of clarity in cellular detail if the specimens were left at room temperature more than thirty minutes after death. It is believed that the small interval between sacrifice of the animal and completion of the finished section contributed in no small measure to the reproducibility of the findings.

The procedure is the same with Reagents I, IV, and V. The fresh section is placed on the freezing microtome over a piece of damp tissue paper which aids in the adherence of the specimen. Sections of about 15 microns are then cut, placed on a clean slide by means of a brush, and left uncovered until dry. This is necessary in case of Reagent V, to avoid precipitating stannous hydroxide. When dry, one drop of the reagent is added, a cover slip is placed over it, and the excess of the reagent blotted away. Then the edges of the cover slip are sealed with commercial gold size.* It is imperative that the cover slips be well sealed because of the pronounced humectant and creeping properties of the glycerin. The entire sectioning, mounting, and testing with reagent can be finished within ten minutes. The reagents act promptly and the slides are ready for reading ten minutes after they are made. Slides prepared with Reagent I, which is routinely used as a control, as well as those prepared with Reagent V, usually remain unchanged for at least two weeks.

It may be noted here that tissue sections which contain both mercurous and mercuric ions can give a misleading impression if they are read too long after the application of the thioglycollic acid reagent (IV). The reason for this is that free mercury will react with mercuric mercury in a complex oxidation-reduction

*Commercial gold size is the type of adhesive used for applying gold foil to plate glass.

system. Additional free mercury is liberated during the process. This reaction is slow, in the sections, so that no visible change is observed over a period of several hours. Twenty-four hours later, however, the globules may have become more numerous and larger. One may take advantage of this reaction, if one wishes to establish the presence or absence of submicroscopic quantities of mercurous mercury in a tissue known to contain mercuric ions. If there has been any mercurous ion present it will have manifested itself as mercury after several days because of the reaction described above. Under ordinary circumstances, we recommend that slides treated with reagent IV be photographed or read within a few hours.

Fig. 1.—Section of skin of a rabbit treated with a metallic mercury cream. The metal can be seen within the stratum disjunctum and in the cutis.

In general, extreme precaution should be taken to insure the freedom from mercury of all equipment. The microtome knife in particular, should be inspected frequently for adherent mercury. Dusts are sometimes troublesome, unless sections are kept covered whenever practicable. It is more conservative practice to withhold a positive identification of mercury unless at least some of the spheres can be seen within the substance of the section, or unless microchemical proof is undertaken.

TYPICAL FINDINGS

Metallic Mercury.—In our experiments, metallic mercury seldom occurred free in the body tissues. We have confirmed Zwick's observation that it may be seen in the subcutis following percutaneous inunction.[2] As he noted, the globules gradually lose their gloss and become roughened as though in process of chemical change. In in vitro experiments we noticed that a similar phenomenon takes place. When mercury is placed in physiologic saline, the droplets gradually lose their shininess. A grayish film appears. Calomel forms and the solution becomes alkaline. It appears probable that the tendency of mercury to react with components of the circulating fluids is responsible for the apparent failure to appear in the organs in metallic form.

We have further confirmed Zwick's finding that mercury globules are easily displaced during sectioning. We know of no certain remedy for this, but we repeat the suggestion that thick sections (15 microns) be used. Zwick thought to minimize the error, or at least to have it operate in his favor, by sectioning from within out. To this may be added the precaution of lowering the section on the reverse stroke of the microtome, so that the globules are not displaced backwards by the blade.

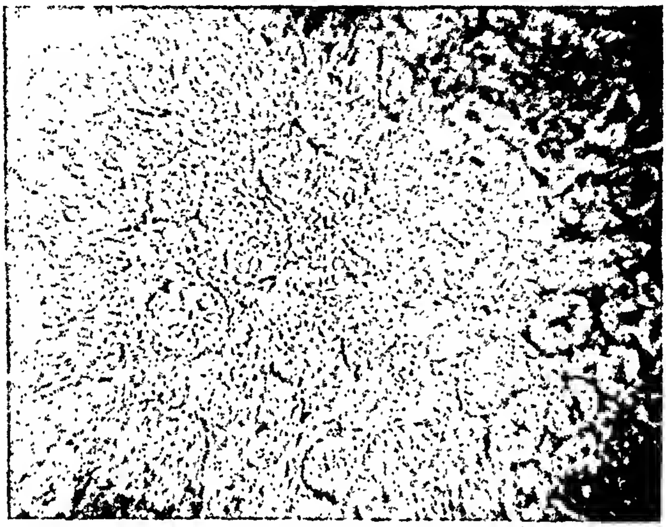

Fig. 2.—Section of kidney of a mouse injected intravenously with mercurous acetate showing mercury within the tubules.

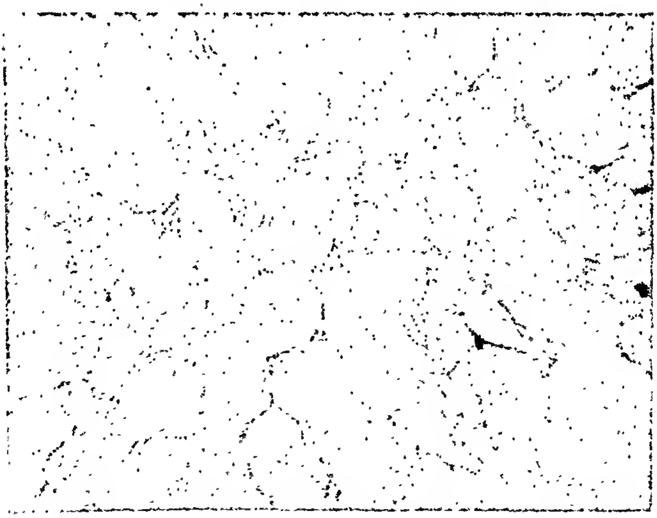

Fig. 3.—Section of kidney of a mouse injected intravenously with mercuric acetate showing mercury within the tubules and interstitially.

Fig. 1 shows the appearance and distribution of metallic mercury in the skin twenty-four hours after innuction from a vanishing cream vehicle.[9]

Mercurous Mercury.—Within a few minutes after the intravenous injection of mercurous acetate in laboratory animals (rats, rabbits, guinea pigs), both

mercurous mercury and mercuric mercury are found in the parenchymal cells and endothelial cells of the kidney. The latter form is preponderant. Even plain whole blood appears to have the capacity to oxidize mercurous salts to the mercuric form in vitro with great rapidity. We do not know what albuminates or complexes may form in the process, but the evidence that oxidation has taken place is based on the specificity of the thioglycollic acid reaction. It may be that subsequent metabolic or excretory processes ultimately lead to a reduction of valency, but the first effect is certainly one of oxidation. Fig. 2 shows mercurous mercury in the kidney of a mouse which had been poisoned by mercurous acetate.

Mercuric Mercury.—It was expected from the preceding observations that the divalent derivatives of this metal would appear in the liver and kidney as mercuric mercury. This proved to be the case. Systematic histochemical examinations have not been carried on over a long enough period of time to permit comment as to possible ultimate changes in valency of mercuric mercury in the body. Such a study might be of value in elucidating the questions of toxicity and excretion.

Fig. 3 shows the characteristic distribution of mercuric mercury in a mouse killed with mercuric acetate.

SUMMARY

Histochemical methods for the determination of mercury have been reviewed and some modifications suggested.

The use of thioglycollic acid for the histochemical differentiation of mercurous and mercuric mercury has been suggested and a method of procedure has been described.

We should like to thank Dr. S. W. Lee, Mr. Thomas Maren, Dr. Franz Herrmann, and Dr. Marion B. Sulzberger for constructive criticism and comment.

LABORATORY METHODS

GENERAL

A SIMPLE MICROMETRIC APPARATUS FOR DETERMINING THE SEDIMENTATION RATE OF THE ERYTHROCYTES*

JULIAN L. ROGATZ, M.D., NEW YORK, N. Y.

SINCE Fahraeus first noted the significance of erythrocytic sedimentation in blood plasma, in 1918, this apparently simple phenomenon has been studied with increasing interest. Its usefulness in determining the presence or absence of infection in the body has been amply verified. Our present understanding of the erythrocytic sedimentation rate, its mechanism, behavior and significance in various diseases, has been admirably summarized by Cutler.[1]

Though the test has been generally accepted and is in constant daily use, there is no agreement as to a suitable apparatus for measuring the rate of settling of the red cells. Unwieldy arrangements with long tubes of wide bore, requiring comparatively large amounts of blood drawn from a vein, have given way to simpler and more practical devices utilizing tubes, or even pipettes, with much narrower bores, requiring not more than a drop of blood easily drawn from the tip of a finger; this is a great advantage in pediatric practice, permitting serial tests with little or no complaint from young patients.

There have been many of these micromethods, which have proved reasonably accurate. The technique usually requires the mixing of blood and anticoagulant separately before placing into the sedimentation pipette. In 1938 I compared what seemed the simplest of these methods, that described by Smith in 1936,[2] with the highly accurate Cutler macromethod and found it equally accurate.[3] Smith feels that in tubes of narrower bore than 2.5 mm. capillarity with its inherent drawbacks cannot be avoided. Thus his remains the only tube available in which capillarity does not occur and in which the figures can be compared directly with a standard venipuncture method. Though the merit of Smith's method may not be denied and its technique is easily mastered, it presents certain objections which militate against its general use by the practitioner and which must be eliminated in the ideal apparatus.

I referred at that time to the Landau modification of the early Linzenmeier-Raunert technique,[4] which seemed to fulfill most of the requirements of an ideal test, i.e., the drawing and mixing of blood and anticoagulant, and the sedimentation of the cells took place in one pipette, thereby eliminating all unnecessary,

*From the Abraham Jacobi Division for Children of the Lenox Hill Hospital, Service of Dr. Jerome S. Leopold.

Received for publication, May 30, 1943.

intervening steps. Careful sealing of the tip of the pipette to prevent loss of the contained specimen in the vertical position seemed a problem. A capillary pipette, similar to that used for the counting of white cells, was used. The column of blood was controlled by a "check syringe" device, which was fitted over the pipette and removed before setting into the rack. The gadget seemed complicated and was not available in this country.

During the past year, however, the Landau apparatus was manufactured locally,* and the "check syringe," on which the usefulness of the method depends, was simplified into an "aspirator" consisting of a metal screw and collar, which fits into a small piece of thick rubber tubing, the whole device being no more than two inches long and one-half inch wide.

The utter simplicity of this apparatus, which consists of only three parts, a pipette, an aspirator, and a rack, and permits of no further simplification of the sedimentation rate technique, impelled me to study its accuracy. I decided to use the proved Smith-Cutler tube as a control. Cases were taken at random as they entered the wards, usually older children because of the cooperation necessary for the drawing of the somewhat larger amounts of blood required for both tests, performed simultaneously. The results of the study on 100 cases, comprising 200 tests and deemed adequate, are presented in the accompanying table (see Table I).

APPARATUS

The Landau microsedimentation apparatus (see Fig. 1) consists of:

1. A capillary pipette 12.5 cm. long with a capillary bore 1 mm. in diameter, expanded into a bulb or mixing chamber 3 cm. from the upper end. Markings are etched at 12.5 mm. and 62.5 mm. from the lower tip, providing for a column of blood 50 mm. long and 1 mm. wide. The intervening space is graduated in millimeters.

2. An "aspirator" consisting of a metal screw with a milled head and its collar, 3.5 cm. long, which fits snugly into a piece of thick rubber tubing 4.5 cm. long. When screwed down, the entire length of the aspirator is 5.5 cm. Turning the screw in either direction controls the position of the column of blood in the pipette, over which it is fastened. When the screw is stationary, the column remains fixed.

3. A metal rack of simple construction with a rubber-cushioned floor and an adjustable rubber-cushioned cap. A hidden spring device in the floor permits depression of the base and holds the pipette vertically and hermetically sealed.

Control apparatus: the Smith micromethod described in a previous study.[2]

PROCEDURE

The upper end of the Landau pipette is fit into the rubber end of the aspirator, which is screwed tightly down. Holding the pipette in the palm of the hand, daggerlike (see Fig. 2), so that the thumb and the index finger control the screw, 5 per cent sodium citrate is drawn up into the pipette by revolving the screw, to the 12 mm. mark. A droplet of blood is then drawn from

*By the Clay-Adams Co., Inc., 44 East 23rd Street, New York City.

the pricked finger, as in a blood count, until the column reaches the 62.5 mm. mark, avoiding air bubbles by keeping the tip of the pipette in constant contact with the blood as it is expressed. Wipe the tip of the pipette clean to prevent later clotting of the blood at this point. The blood and citrate are thoroughly mixed by drawing the column into the ampula or chamber, stopping the lower meniscus a few millimeters below the opening of the chamber to avoid air bubbles. The column of blood is alternately depressed and raised, thus emptying and filling the chamber about seven times to insure proper mixing. The column is finally screwed down until the upper meniscus reaches the mark just below the mixing chamber. The lower tip of the pipette is pressed into the rubber floor of the rack while disengaging the aspirator. The upper end of the pipette is placed beneath the cap of the rack, where it will be held snugly and vertically. After standing for one hour, the millimeter level to which the red cells have fallen is read. The drawing and mixing of blood prior to the beginning of sedimentation should not take more than thirty seconds. The pipette should be cleaned with alcohol and ether after use.

The normal figures reported by Landau were 1 to 6 mm. for men and children under two years; 1 to 9 mm. for women and children over two years; 10 to 15 mm. were considered slightly increased values; 16 to 30 mm. moderately increased; over 30 mm. high. In general I think it sufficiently accurate to consider values under 10 mm. at the end of one hour normal and those up to 15 mm. slightly increased or "high normal" beyond which the rate has increasing significance.

COMMENT

Rapid sedimentation is dependent on the formation of red cells into large clumps or rouleaux, induced by alterations in the plasma, mainly an increase in fibrinogen, which results from the accumulation in the blood stream of certain products of tissue destruction during infections, certain intoxications, malignancy, etc. Cutler thought this change in the plasma proteins plays its predominant role in rouleaux formation, probably through surface dehydration or change in water balance on the surface of the red cells. Globulin, albumin, cholesterol, and electrolytes are involved to a lesser extent.

Smith contended that the influence of capillary exerted within the lumen of the narrow tube and the tendency to clot formation were inherent drawbacks in the pipette methods, but Morrison[5] indicated that the length of the tube used does not affect rouleaux formation, nor does the diameter as long as the tube remains perpendicular. Acceleration of sedimentation in tubes deviating from the perpendicular is dependent on the relative increase in vertical pathways or columns of falling cells. The smaller the diameter of the tube, the greater will be the relative increase in vertical pathways. Though Smith feels the capillarity present in tubes of less than 2.5 mm. bore a disadvantage, this has not proved sufficient in practice to materially affect the accuracy of the pipette method. Clotting of blood in pipettes happened but twice in this series and is therefore not a major objection.

The results obtained in this study correspond satisfactorily in all but four cases, those numbered 37, 42, 75, and 81. In each of these the rate in the Landau

pipette was well within normal limits while the Smith reading was slightly increased. Thus, in Case 37, there was a tonsillectomy in an apparently well child (the Smith reading was 15 mm. at the end of one hour while the Landau reading was 7 mm.). In Case 75, that of a child with purulent otitis media, the

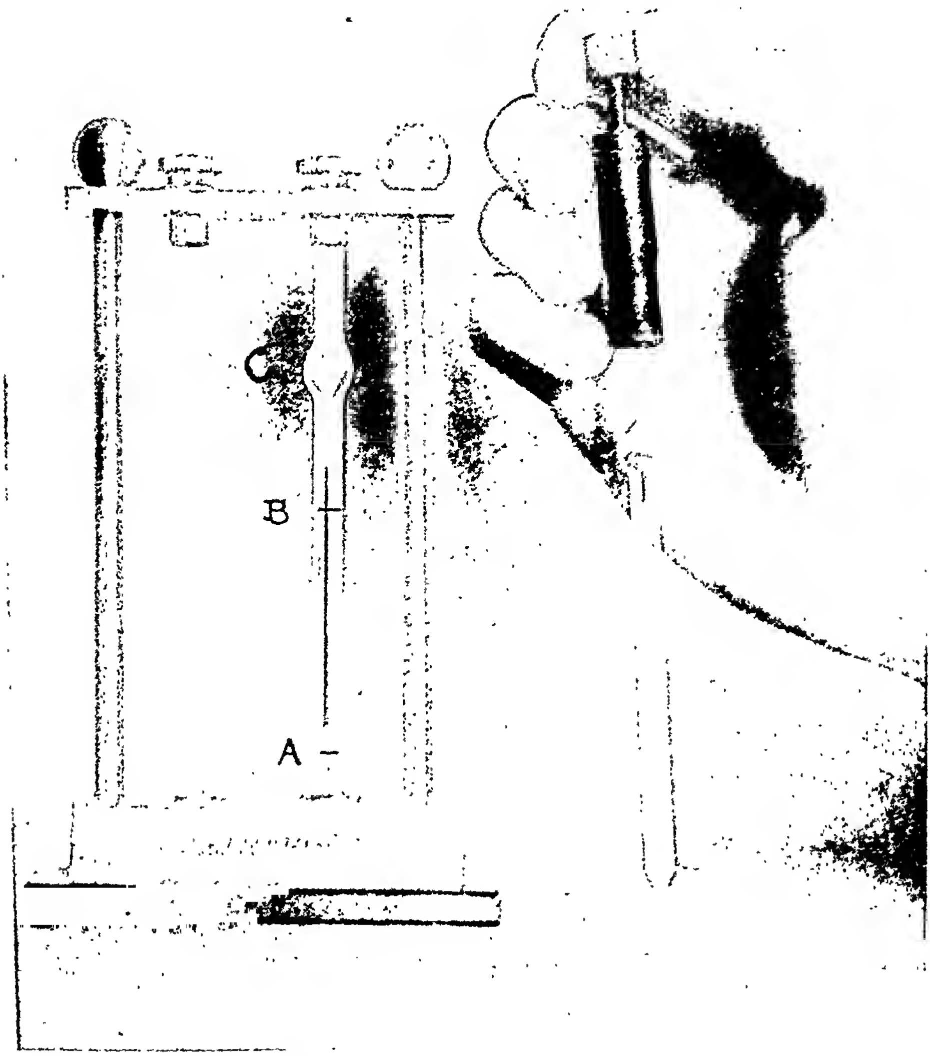

Fig. 1.—Showing Landau micrometric apparatus for sedimentation of the erythrocytes, consisting of metal rack for two pipettes, with one pipette in place, and the rubber aspirator, attached to the other pipette, held in hand. Sodium citrate 5 per cent is drawn to the 12.5 mm. mark (*A*) and blood is then drawn up to the 62.5 mm. mark (*B*), after which the column is drawn into the mixing chamber (*C*). Note specimen of blood in chamber of the pipette with aspirator and note that blood is not drawn completely into the chamber, thus avoiding air bubbles. The pipette in the rack contains a sedimenting column of blood.

Smith reading of 15 mm. seemed more related to the clinical state than the corresponding Landau value of 4 mm. The most marked discrepancy occurred in Patient 81, recovering from an acute tonsillitis, whose rate according to the Smith method was 17 mm. and only 7 mm. by the Landau method.

In the remaining 96 cases the figures corresponded favorably. In some, the high values were somewhat higher in the Landau pipette, while in others

Fig. 2.—Showing method of holding pipette with aspirator attached as blood is withdrawn from tip of a finger.

this was true of the Smith-Cutler tube. The variations, as high as 18 mm. in one case, averaged 7 mm. in 33 patients in whom the higher value appeared in the Landau tube. In 18 cases the situation was reversed, the higher values appear-

ing in the Smith-Cutler tube, the greatest variation being 12 mm., the average 5 mm. These differences are not great when it is considered that they occurred in sedimentation rates which were very rapid. They are, therefore, not significant.

After reading a number of sedimentation tests, it soon becomes apparent that there may be two types of reaction. The separation of red cells from plasma is usually indicated by a sharp demarcation. Frequently, however, it may be diffuse or blurred. This happens occasionally in other tubes with larger bores, as it did a number of times in the Cutler tubes. It is most likely to occur early in

a test the sedimentation of which proves rapid. There is a gradual tapering of color from above downward, the pale plasma deepening into the pinkish color of sinking erythrocytes, which merges into the deep red of packed cells. By the end of an hour the blurring was usually replaced by a sharp line. In only nine cases of this series did blurring persist after one hour. In Case 36 it cleared in seventy minutes.

As the cells pack, the diffused area covers only a few millimeters and the line of probable demarcation can be easily estimated within one or two millimeters, which is sufficiently accurate for all practical purposes. If a reading is deemed unsatisfactory, it is possible to reattach the aspirator to the pipette, start drawing the column into the mixing chamber before releasing pressure on the floor of the rack, and allow the cells to sediment anew, provided the blood has not clotted in the pipette. The second reading may be more satisfactory.

SUMMARY

The new Landau microsedimentation apparatus is described, and its reliability is demonstrated in a series of 100 cases, in which the proved Smith-Cutler method was used as a control. The apparatus and technique have been reduced to their simplest possible form by successfully combining the several necessary steps, namely, the drawing and mixing of blood and anticoagulant and the sedimenting of the red cells, into one uninterrupted procedure accomplished in one pipette. Only three pieces of apparatus of the simplest possible construction are required: the pipette, an aspirator, and a rack. Not more than $\frac{1}{20}$ c.c. of blood is used, and the time required from puncture of the finger to the beginning of sedimentation is about thirty seconds. The set is so compact that it may be placed in a small corner of one's bag. No previous experience or unusual skill is necessary for the efficient use of this method. A test of acknowledged significance thus becomes universally available to practitioner and specialist alike, equally useful at the bedside or in the laboratory.

CONCLUSION

The new Landau erythrocytic microsedimentation test fulfills the requirements of the ideal method. It is deemed worthy of further trial. Its reliability having been adequately demonstrated, it is suggested that this technique and apparatus may help to establish the desired standardization of the sedimentation rate test.

PORTABLE APPARATUS FOR ESTIMATING THE PERIPHERAL BLOOD FLOW IN SHOCK*

HERBERT S. WELLS, M.D., AND JOHN J. THOMPSON, A.B., WINSTON-SALEM, N. C.

SKIN pallor in shock suggests that the peripheral blood flow is reduced, but it is difficult to estimate the degree of this reduction from the intensity of the pallor or other clinical signs. The one series of measurements carried out on human cases[1] indicates the usefulness of quantitative information on blood flow for gauging the degree of developing circulatory failure and the response to transfusion. The direct plethysmographic method, however, commonly used to measure blood flow, requires cumbersome equipment not easily adapted to studies at the bedside or in the operating room or casualty station. The method to be described, while not so accurate as the more elaborate equipment of the physiologic laboratory, is practical in that it gives consistent readings which serve well for comparative studies, and because the apparatus is portable and easy to operate.

The apparatus is essentially a small air plethysmograph consisting of a cuff, 1¼ inch wide, which supports a thin rubber bag against the skin. As the limb swells, following quick inflation of a centrally located sphygmomanometer cuff, air is expelled from the cuff bag, whence it passes to one end of a horizontal pipette (1 c.c. calibrated in 0.1 c.c. units) containing a droplet of water, the movement of which measures the rate of swelling of the limb. The distal end of the pipette connects to a second rubber bag upon which a lead weight floats. This constant pressure or "reservoir" bag (*R B* in Fig. 1) maintains a nearly uniform pressure of 6 cm. water in the whole system, which is sufficient to inflate the cuff for contact with the skin. Movement of the water drop is timed by counting swings of a pendulum whose period is 0.5 second. The number of pendulum swings for successive 0.1 c.c. excursions of the water drop are recorded. These data, together with the volume of the limb enclosed by the cuff, which is indicated by markings on the cuff, enable calculation of the blood flow in c.c. per 100 c.c. of limb per minute. An alignment chart is used, in practice, to facilitate the calculations.

It has been found that the cuff bag need not completely surround the limb. A bag 7 inches long, made from ¾ inch Penrose drainage tubing and cemented to a cuff 15 inches in length, may be applied to a limb segment of volume up to 250 c.c. For use on the leg a longer cuff and bag may be required.

Several forms of the apparatus have been designed, but the most compact and readily portable type, shown in the upper sketch of Fig. 1, has proved most practical. All necessary equipment except the sphygmomanometer (aneroid

type) is contained in a box which is $4\frac{1}{4}$ x 9 x $1\frac{1}{4}$ inches when closed. The traps, *T* in the diagram, which prevent loss of the water drop, enable the box to be carried in any position. The pipette is mounted on a strip of wood, which may be turned forward, allowing the water traps to lie in a horizontal position so the cover may be closed. The cuff, the metal paper clip (not shown) used for holding the cuff in place on the limb, and a tourniquet for the wrist (18 inches of 1 inch Penrose tubing) may be placed in the box when not in use. A short thermometer, suitable for measurement of the skin temperature, is held in the upper part of the metal clip shown inside the cover of the box. The lower part of this clip serves to clamp the pendulum when not in use.

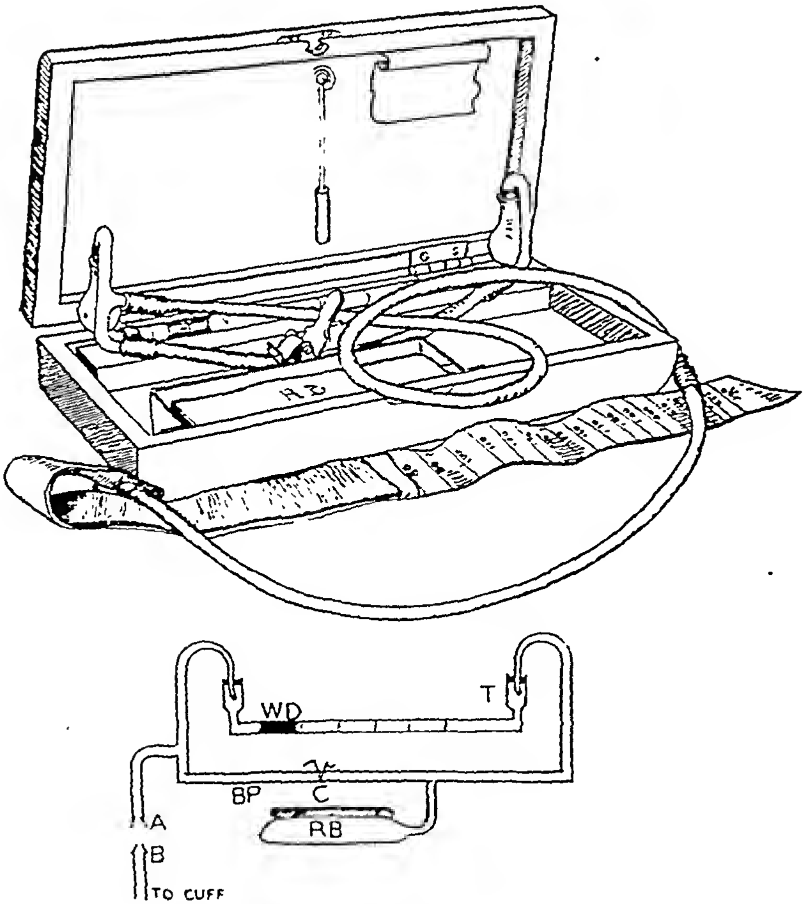

Fig. 1.—Drawing and diagram of blood flow apparatus. *W D*, water drop in 1 c.c. pipette; *T*, water traps at each end of the pipette; *A* and *B*, metal connectors on tubing to the cuff bag; *B P*, by-pass tube, which is opened or closed by clamp, *C*; *R B*, reservoir bag, 4 inches long, similar to the cuff bag, and having a lead weight of 150 Gm. "floated" upon it.

A by-pass, *B P*, which is closed by the clamp, *C*, during the determination, is opened to allow air to pass between the cuff bag and the reservoir bag during inflation of the bag system or during movements of the patient which might otherwise cause the water drop to be blown out of the pipette. To inflate the bag, the cuff is first fitted snugly, but not tightly, to a segment of the arm or leg,

which should be as nearly circular in cross section as possible. The metal tubing connectors, *A* and *B*, are separated. The operator blows into *A* until the reservoir bag, *R B*, is inflated. Pinching off the rubber tube above *A*, he then connects *A* and *B*. When the tube is released, air from *R B* passes back into the cuff bag.

Spontaneous variations of blood flow are reduced to a minimum, if the circulation to the hand is occluded by a tight tourniquet of Penrose tubing wrapped tightly just above the wrist.

The accuracy of the method was tested by comparison of simultaneous recordings, which measured the swelling rates following venous occlusion of (a) the whole forearm inserted in a water-jacketed air plethysmograph and (b) of a segment of this forearm, encircled by the cuff plethysmograph. For recording purposes a slightly modified form of the apparatus was used in which the reservoir bag system was replaced by a constant pressure water reservoir, from the open end of which air was displaced at atmospheric pressure to a volume recorder. A second recorder registered the displacement of air from the larger plethysmograph. The recorders consisted of soap films formed across the ends of horizontal glass tubes. Images of the bubbles, which increased in size and approached each other as air entered from the respective plethysmographs, were projected at convenient magnification across the horizontal slit of a 12 cm. recording camera. Time in seconds, calibration lines for the two recorders, and a mercury manometer record of the pressure applied to the collecting cuff were also photographed. Soap film recorders (first used in this laboratory) respond to pressure changes of less than 0.005 mm. H_2O; and errors of amplitude, time lag, and maximum rate of response during tests, with simple harmonic volume changes, are imperceptible up to a frequency of 3 to 5 cycles per second. The natural frequency of the larger recorder was 12 to 15 per second.

The cuff plethysmograph, as tested in this manner on 5 normal subjects (23 determinations) gives values of the blood flow, per unit volume of limb, which are regularly low. The mean error is -28 ± 11.3 per cent, the range being from -10 to -47 per cent.

It is evident that the absolute values obtained cannot be relied upon to give better than an estimate of the actual blood flow. The readings, however, are consistent and reproducible, and comparative measurements are reliable. Furthermore, the variability (standard deviation as per cent of the mean) of readings on normal subjects is not greater than is the case for more accurate methods. The mean of measurements on 54 normal subjects was 2.65 ± 0.96 c.c. per 100 c.c. per minute. All subjects were comfortably warm, at room temperatures between 21° C. and 30° C. and with forearm skin temperatures from 29° C. to 34° C.

In most cases it makes no difference whether the cuff is placed around the upper, middle, or lower third of the forearm; the same value for blood flow is obtained in each case. This indicates a remarkable uniformity (from which, however, some subjects show considerable departures) of the swelling of all portions of the limb. It seems evident that the chief cause of the error of the cuff plethysmograph is referable to the slight compression of blood vessels lying be-

neath it rather than to the location of the cuff on a portion of the arm which swells at less than the average rate for the limb as a whole.

During the past year the method has been tried in clinical practice in several hospitals on over a hundred patients, including a number suffering from various forms of circulatory failure (cardiogenic, vasogenic, hematogenic types). The cases, briefly reported in Table I, may suffice to indicate the low levels of peripheral blood flow found in hematogenic shock. The increase of the flow to or toward normal levels, following transfusion, is noteworthy. The tendency of the blood flow to vary inversely with the hematocrit readings in Case 4, is of particular interest, since a blood flow determination may be made in a fraction of the time required for a hematocrit. In general, we may say that a blood flow value of less than 1.0 c.c. per 100 c.c. per minute, which persists after pain, nausea, cold, or other confusing factors have been eliminated, is highly suggestive of peripheral circulatory failure of the hematogenic type. Further clinical studies will of course be necessary to determine the range of usefulness of the method.

TABLE I

CASE NO.	TIME AFTER INJURY	BLOOD PRESSURE	HEMATOCRIT	BLOOD FLOW	REMARKS
	hours	mm. Hg	per cent cells	c.c. per 100 c.c. per minute	
1	5	96/60	-	0.8	Gastroenterostomy followed by profuse hematemesis, seven hours. Transfusions, whole blood, 1500 c.c. to tenth hour; 1000 c.c. twenty-first hour.

	21	120/76	-	2.4	
2	1	50/?	-	0.5	Stab wound of thorax. Transfusion 500 c.c. whole blood first to fifth hours. Bleeding not controlled until third hour.
	3	68/?	-	0.6	
	5	110/74	-	1.1	
3	4	50/?	-	0.7	Post-partum hemorrhage. Transfusion, 800 c.c. glucose, 500 c.c. plasma from fourth to sixth hours.
	5	108/80	-	2.7	
	6	120/82	-	3.6	
4	0.5	-	38.2	-	Severe second degree burn. Received 5300 c.c. plasma during thirty hours.
	6	-	45.2	2.3	
	17	-	58.8	0.6	
	108	-	38.7	2.5	

The blood flow apparatus serves a second useful function in shock cases, for it enables one to determine the systolic blood pressure in those patients (unexpectedly numerous, in our experience) in which the usual methods fail and the pressure is reported as "unobtainable." As the sphygmomanometer cuff pressure is lowered to the systolic level, blood entering the forearm, even if its weak pulsations cannot be heard with the stethoscope or palpated at the wrist, will cause the water drop in the pipette of the blood flow apparatus to move. A very sharp measure of systolic pressure can always be determined in this way.

A RESPIRATORY CHAMBER FOR CHRONIC EXPOSURE TO GASES*

A. T. MILLER, JR., CHAPEL HILL, N. C.

THE respiratory chamber described in this paper is a modification of the one used by the author in previously reported work (Miller, 1940[1]) on the effects of chronic exposure to carbon dioxide. The apparatus itself has not previously been described. The chamber now in use in this department was designed specifically for studies on chronic carbon monoxide exposure, but is readily adaptable to the study of other toxic gases, including war gases.

The over-all dimensions of the chamber are 11 feet by 7 feet by 6 feet. The actual gas chamber is 8 feet by 7 feet by 6 feet, giving a capacity of 336 cubic feet. The remainder of the capacity is accounted for by the space between the double entrance doors. The chamber will readily accommodate three human subjects, or 12 dogs, or 200 rats.

The chamber is constructed of 24 gauge sheet metal placed over a framework of two by fours. The metal is fastened to the framework with galvanized nails so that the junction between nail heads and sheet metal can be soldered. All seams are soldered and the entire chamber is painted inside and out with heavy floor enamel. Control experiments indicate that a gas mixture placed in the chamber suffers no measureable change in composition during forty-eight hours.

The chamber has a wooden floor elevated four inches from the sheet metal bottom and sealed to prevent trapping of gases between the two. The entrance doors are built of 1½ inch redwood, reinforced by 1 inch angle iron to prevent warping. The door overlaps the door facing 2 inches on all sides, and when the door is closed, it is sealed by a gasket consisting of rubber tubing set in a continuous groove on the inner surface of the door overlap. Each door is closed by two commercial cold room handles which exert enough pressure to collapse the rubber tubing gaskets against the door facing. The double door entrance minimizes changes in gas composition produced by entering and leaving the chamber during the course of an experiment.

Two windows, each 3 feet by 2 feet, are placed in the chamber for illumination and observation. Additional illumination is provided by an overhead light bulb, and an even mixture of gases is maintained by an oscillating fan. Electric wires are led into the chamber through porcelain insulators and are sealed with cement.

A continuous circulation of air through the chamber maintains a normal pressure of oxygen and removes carbon dioxide. As shown in Fig. 1, this circulation is provided by an 8 inch electric fan mounted directly into a funnel-like expansion of the 4 inch tube leading into the chamber. A 4 inch exit tube leads

to the outside of the building. The gas to be studied is led into the ventilating tube through a side tube as shown in the diagram.

The maintenance of a desired gas concentration in the chamber requires two things: a constant rate of ventilation and a constant rate of flow of the gas into the ventilating tube. Flowmeter tests indicate that an electric fan kept in good working condition maintains a very constant ventilation rate. A constant inflow of gas requires a source of gas under a constant pressure, with adjustment of the rate of flow by suitable reducing valves. Illuminating gas is a convenient source of carbon monoxide in amounts large enough for continuous flow. The low pressure at which this gas is ordinarily delivered and the fluctuations in rate of flow require a system for storing the gas under pressure for delivery to the gas chamber. The details of this system are shown in Fig. 1. The gas flows from the jet into a 50 liter Tissot spirometer. This serves as a reservoir from which gas is compressed into a pressure tank. The compression pump is a Crowell rotary number OD with a maximum pressure rating of 25 pounds and a free air flow of 2 cubic feet per minute. The pump is operated by a ¼ H. P. motor. The pressure tank is equipped with an automatic pressure regulator ("Pressuretrol" type L 404-2, made by the Minneapolis-Honeywell Regulator Company) with a pressure range of 2 to 50 pounds. This pressure regulator is connected to a pump motor through a Colt "Noark" automatic switch. The pressure regulator is set for a cutin pressure of 18 pounds and a differential of 2 pounds, so that gas is always delivered from the pressure tank to the respiration chamber at a pressure between 18 and 20 pounds. The outlet from the pressure storage tank is provided with a gate valve for cutting off the flow completely at the end of an experiment and with a Hoke ammonia control valve for fine adjustment of flow. This valve permits accurate control from full flow down to 5 bubbles per minute. In practice, the concentration of carbon monoxide in the respiration chamber can be controlled within 0.001 per cent during a 6 hour exposure period.

The absolute variation in rate of flow of gas into the tank may be determined as follows. Gas is delivered from the storage tank at a pressure which steadily declines from 20 to 18 pounds over a period of about ten minutes. At this point, the pump cuts on and the pressure is built up to 20 pounds again in about one and one-half minutes. The average delivery pressure then is 19 pounds with a range of ± 1 pound, or 5 per cent of the total pressure. This means that a given rate of flow can be maintained within the limits of ± 5 per cent, and this is proved by the fact that the fluctuations in the flowmeter reading are uniformly within these limits (see Fig. 2). If a still more uniform rate of flow is necessary, it can be obtained either by using a pressure regulator with a smaller differential range or by inserting a constant flow valve (such as those used on oxygen cylinders) between the pressure tank and the respiration chamber.

The operation of the entire gas flow assembly is made completely automatic by providing the bell of the Tissot spirometer with an automatic checking device. The rise of the bell is checked at such a height that the depth of the bell below the water level is greater than the gas pressure in the main, in centimeters of water. The pressure in the bell increases until it equals the main pressure and the flow of gas from the main ceases. Guy ropes attached to the top of the spirometer bell check it at the desired point.

The concentration of carbon monoxide in the respiration chamber may be determined by the usual analytic methods. A great saving of time and effort is made by the use of a carbon monoxide indicator (Mine Safety Appliances Company) which requires only about two minutes for a determination.

Routine determination of the carbon monoxide concentration in the chamber may be obviated in the following way. The flowmeter is calibrated against the carbon monoxide concentration in the chamber throughout the range of concentrations to be used. It should be emphasized that this calibration must be experimental, since the logarithmic relation between flowmeter pressure differential and rate of flow breaks down at rates of flow high enough to produce turbulence. Once the calibration is performed, the desired carbon monoxide concentration is obtained by adjusting the fine control valve to give the proper flowmeter reading. The oxygen and carbon dioxide concentrations should be checked occasionally, although they have never been found outside normal limits in work in this department. The relative humidity is recorded at the end of an exposure period by the wet bulb method. This may be done without entering the chamber by inserting the wet bulb thermometer through a rubber stopper into a flask through which a stream of air from the chamber is drawn by suction. The relative humidity has never been observed to rise above that of the outside atmosphere even with a full complement of experimental animals in the chamber.

If the effects of carbon monoxide are to be studied uninfluenced by other constituents of illuminating gas, these constituents must be removed. Most artificial gas is a mixture of coal gas and water gas. The Chapel Hill city gas has the following percentage composition:

Carbon monoxide	23.4
Hydrogen	36.8
Methane	17.8
Illuminants (unsaturated hydrocarbons)	8.6
Nitrogen	8.5
Carbon dioxide	3.7
Oxygen	1.2
Benzene (not included in analysis furnished by gas company but usually present to the extent of 1 or 2 per cent).	

This is a characteristic composition for manufactured gas, although the relative proportions of the constituents may vary in different communities. Of these, hydrogen, nitrogen, and methane are simple asphyxiants; that is, they are inert gases which act by excluding oxygen from the lungs when present in high concentration. The unsaturated hydrocarbons have anesthetic properties in high concentration (about 60 per cent), but are simple asphyxiants in low concentrations. All of these gases are present in extremely low concentration in the final mixture of air and gas delivered to the chamber (less than 0.2 per cent for the sum of all of them when the final carbon monoxide concentration is 0.05 per cent) so that their effect is negligible and they need not be removed. The final concentration of carbon dioxide under the same conditions is less than that of atmospheric air. Benzene is the only constituent aside from the carbon monoxide which is present in sufficiently high concentration to exert specific effects. The greater toxicity of illuminating gas compared with pure carbon

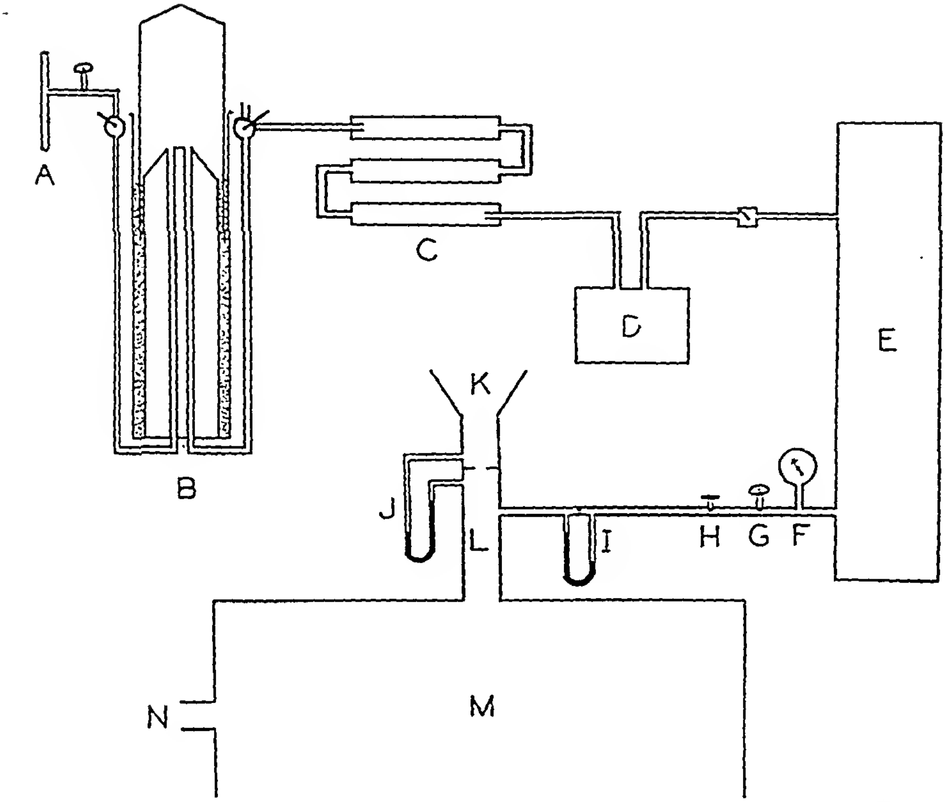

Fig. 1.—Diagram of assembly for controlling gas flow and ventilation. *A*, gas main; *B*, Tissot spirometer; *C*, charcoal absorption tubes; *D*, compression pump; *E*, pressure storage tank; *F*, pressure gauge; *G*, gate valve; *H*, reducing valve; *I* and *J*, flowmeters; *K*, position of ventilating fan; *L*, ventilation tube; *M*, gas chamber; *N*, exit tube of ventilating system. The motor which operates the pump and the automatic pressure control are not shown in the diagram.

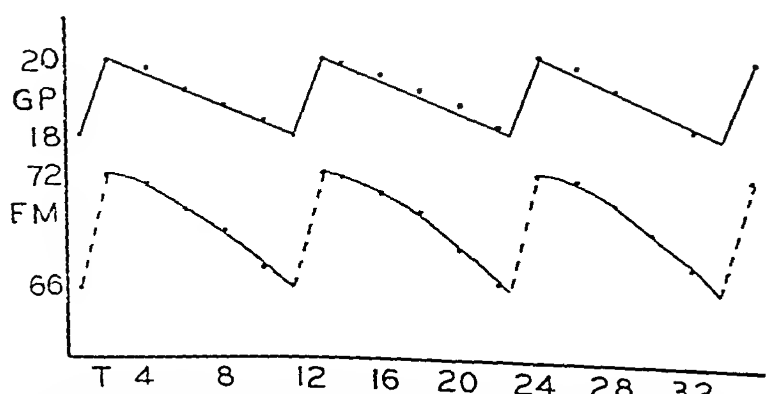

Fig. 2.—Relation between storage tank gauge pressure and rate of flow. Abscissa, time in minutes. Ordinate, *FM* = flowmeter readings in mm. glycerin, *GP* = gauge pressure in pounds.

monoxide is usually attributed to the presence of benzene. This may be removed quantitatively from the illuminating gas by passage through absorption tubes containing activated charcoal, as shown in Fig. 1. The completeness of removal may be tested by bubbling the gas through a test bottle containing a dilute solution of formaldehyde in sulfuric acid (5 c.c. of 40 per cent formaldehyde diluted to 100 c.c. with concentrated sulfuric acid). A reddish-purple color indicates the presence of benzene.

Only slight modifications are required to adapt the chamber to the use of other toxic gases, including war gases. If the gas to be used is lighter than air, no essential modification is necessary, since the gas leaving the exit tube of the chamber is quickly dissipated by dispersion. If heavier-than-air gases or vapors are to be used, the exit tube should lead through a suitable trap for absorption of the gas or vapor. If corrosive gases, such as chlorine, are used, all surfaces with which the gas comes in contact must be painted with one of the resistant paints now commercially available.

SUMMARY

A respiration chamber and gas train for chronic exposure to carbon monoxide are described. The assembly is automatic in operation and requires no attention during an eight-hour exposure period. The slight modifications necessary for adapting the chamber to the use of other toxic gases are described.

IMMUNOLOGIC REACTIONS FOLLOWING TYPHUS VACCINATION IN ARMY PERSONNEL*

JAMES H. PARK, M.D.† AND FREDERICK M. OFFENKRANTZ, M.D.‡

THE term typhus as generally used refers to three groups of rickettsial diseases: 1. Classical typhus (which includes Murine typhus) and a louse- or flea-borne group. 2. Rocky Mountain Spotted fever, which is caused by a tick-borne group. 3. Scrub typhus and tsutsugamushi fever, which are mite-borne diseases. The known role of typhus as a decimater of civilian and military populations in wartime is too well known to be commented upon further. The form of typhus which has been responsible for this stigma is the Classical group, epidemic throughout Europe. Because of its importance as a public health measure, the War Department, even prior to the present conflict, began immunization of all military personnel destined to enter potential or actual typhus areas. The form of vaccine employed was the rickettsial preparation grown by Cox in the yolk sac of developing chick embryos. Although of proved protective potency in animals, the only large scale trial of this method of vaccination was during the Spanish Civil War, by Rockefeller Foundation workers. Unfortunately they were unable to remain for a period of time sufficient to evaluate their results. The use of vaccine prepared from *Rickettsia prowazeki* (the causative agent of Classical typhus) by the War Department was made standard for personnel going to the Southwest Pacific area as well as points closer to actual epidemic sites of that form of the disease. In the Australasia zone, however, the Scrub typhus or tsutsugamushi group constitutes the endemic and epidemic form. The causative organism here is the *Rickettsia orientalis*.

It is too early to state with assurance that protection has been afforded those exposed to Scrub typhus by immunization with the agent of the Classical form, and complementing this consideration is the fact that no large bodies of our troops have yet been exposed to the Classical form for estimation of the vaccine efficiency.

The inception of our study lay in the need for immunologic data with regard to typhus vaccination in human beings. The method of such study can only be by employing the Weil-Felix reaction. This procedure involves the use of *Bacillus proteus*, the Somatic (O) variety of the X19 and XK strains. The reaction of the Classical group has been to the OX19, while that of the Scrub typhus group has been to OXK. Emphasis has been laid upon the sharp distinction afforded between the groups by the use of this differential reaction. To us in this zone the problem was twofold; 1. What antibody response was being afforded by use of the vaccine. 2. To ascertain serologically the dilution at which agglutination was diagnostic of Scrub typhus.

*From the Third Medical Laboratory, Advance Section, Base Section 2, APO, Postmaster, San Francisco.
†Major, Medical Corps.
‡Captain, Medical Corps.
Received for publication, May 13, 1943.

This study was conducted upon a series of 507 sera collected at random from patients coming through our laboratory for Kahn testing. The blood was collected by venipuncture directly into sterile Wassermann tubes and clotting permitted at room temperature. The serologic testing was performed either immediately or within 24 hours. Where the interval between collection and agglutination was greater than 1 to 2 hours the specimen was placed in the refrigerator. The clot was freed by rimming with wooden applicators; and the specimen was centrifuged at 2000 revolutions per minute for three minutes. Serial dilutions in physiologic saline were made immediately. The dilutions were of the customary strength, i.e., 1:10 to 1:320, except where typhus was definitely suspected, in which case the dilutions went up to 1:2560. The dilutions noted in this paper are those of sera-in-saline, before adding antigen. The final volume of diluted serum was 0.5 c.c. in each instance.

The dilutions were made in duplicate for each serum so that reactions could be obtained against the Proteus X19 and XK ("O," or nonmotile, nonflagellated strain). To these dilutions were added 0.5 c.c. of the bacterial suspensions, prepared for us by the Department of Bacteriology. The Proteus organisms were those of a stock culture obtained from the 9th Corps Area Laboratory, Monterey, California, just prior to our departure for the Southwest Pacific Area, and carried on brain heart infusion agar. As needed, growths were subcultured on the same material and washed off with formalized saline after 48 hours. The suspension was diluted to a number three strength (barium chloride standard, 1 billion organisms). When not in use, the antigen was stored in the refrigerator.

The antigen and serial dilutions were mixed by shaking, and then were placed in the water bath (37 degrees C.) for twenty-four hours. At the end of this time readings were taken in all tubes for: (1) presence of flocculent material on the bottom of the tube, (2) the clarity of the supernatant liquid. Comparison was made in each instance with 3 controls: (1) Antigen-saline: (2) known positive serum; (3) known negative serum. Only those readings were called positive wherein there were both a heavy flocculation and complete or almost complete clarity of the supernatant before shaking. No dilution was called positive where more than an estimated 25 per cent of the antigen remained in suspension. The readings were conducted at the same hour each day, against daylight by the same reader in each instance. It can be stated that variations in all of the technical procedures from venipuncture to cleaning of the tubes was held to an absolute minimum. Only two of the enlisted men participated in the handling of this series.

FINDINGS

Our results are divisible into four categories, which we have arbitrarily set up to include all of the individuals tested. The divisions were created on the basis of relative immunologic probability. As shown in the accompanying table, these were:

1. Civilians, native to this area (except where noted).
2. Patients in the United States Army hospital units, in this area. These individuals had been immunized with the typhus vaccine at various intervals

up to a year and were in the hospital with a definite or suspected diagnosis of malaria, dengue, or syphilis.

3. Men with no clinical evidence of disease (Officer candidates), who likewise had been immunized variously less than a year before testing.

4. Patients who showed titers diagnostic of Scrub typhus.

A fifth group, those who showed positive Kahns, was incorporated into the second group, when it was seen that their responses to the Weil-Felix reaction were the same.

As can be seen in the accompanying table, the civilian group, native to this area, showed absolutely no reactivity to the Proteus either OXK or OX19. It can be stated that none of these individuals admitted having had

TABLE I

TABULATION OF RESULTS

OXK	OX19	POSITIVES	CIVILIANS	OFFICER CAND.	PATIENTS
0	0		36	22	72

1:640	1:80	1			
1:1280	1:40	2			

typhus and that there were no agglutinations, even partial, among them. The eleven civilians who did show reactivity to either or both Proteus strains were all Merchant Marine personnel whose contact with the disease in World ports is highly probable. In the military personnel, immunized as previously described, only 14 per cent showed a reactivity in titers 1:40 or higher (OXK). Of these 7 per cent had reactions with the OXK in dilutions of 1:160 or higher. This last group were in each instance individuals who had a clinical diagnosis of Scrub typhus. Table I will show that although the titers against OX19 rose somewhat in these patients they were still low. The remaining number reacted variously between the 1:40 and 1:160 with the OXK. The OX19 here again were low.

The 86 per cent of the military personnel whose titers were 1:20 or less in either OX19 or OXK demonstrated some very interesting subgroupings. Foremost was the observation that 20 per cent gave no evidence of immunologic

response. The men who were in the hospital for irrelevant illnesses outnumbered the healthy group beyond their ratio within the totals. The second notation and probably the most important single factor was that 60 per cent of the immunized personnel, sick or well, gave absolutely no response to the OX19, while showing a 1:10 or 1:20 response with the OXK.

No attempt shall be made to question the use of the Weil-Felix reaction to interpret immunologic status in typhus. Since the isolation of the *Bacillus proteus* from the urine of typhus patients, agglutination against it has been the only universally accepted clinical procedure for evaluation of the response to the disease. Nor can there be any reasonable doubt as to the selective reaction by the Scrub typhus group to the XK strain, and the Classical group to the X19 strain. As stated above this study set out to utilize these procedures in a mass serologic analysis. Animal protection tests would have been the only alternative method of assay, and this would have been impossible with so many sera.

On this basis, therefore, it becomes evident that in a group of young men, certainly in good health at the time of vaccination, there is a minimal Weil-Felix response to the Cox yolk sac immunization procedure against Classical typhus. This conclusion is inescapable when it is seen that over 88 per cent of the group, whether clinically healthy or suffering from irrelevant illnesses, showed no serum agglutination at all against the OX19. The presence of low titer reactions in the remaining 12 per cent and the high titer in the one individual who admitted having had Classical typhus showed definite potency of our X19 antigen. The question arises as to whether or not the initial two-dose inoculation is sufficient to create an immune response or whether a "series of kick-up" injections are needed. On the other hand, it is most perplexing to find that 80 per cent of the military personnel, ill or well, gave some reactivity against the OXK strain, a great part of them being in the 1:20 dilutions. Since the native population showed no reaction to the Proteus, this immunity may be due to the active inoculation and not subclinical contact with Scrub typhus. Here again, the efficacy of our OXK antigen was proved by the same very high titer responses among the clinically positive group of Scrub typhus patients. The probability here is that the Rickettsia used in the vaccine was that of a strain incitive to antibody response against Proteus OXK. It is understood that workers with this vaccine have recommended a stimulating dose between six months and a year following the initial series. Yet one cannot anticipate a rise to OX19 titers even with stimulation, when the overwhelming evidence indicates lack of response at this time. The interval since inoculation in these troops was in no instance over a year, in 95 per cent less than ten months and in 55 per cent about 6 months. As we observed the accumulating results, there was no reason to attempt their statistical separation on the basis of elapsed time since immunization; all time groups were quite similar.

Our second problem is perhaps of more immediate significance and the findings therewith of less controversial nature. This refers to the titer at which agglutination shall be considered positive for the diagnosis of Scrub typhus. In keeping with the accepted interpretation of findings in the Weil-Felix reaction, OXK titers of 1:160 or higher were considered diagnostic of

the disease. In every instance these patients had been clinically diagnosed as having the disease. Where the titer was clearly 1:80, there was suspicion of the disease, but we did not feel justified in making a positive diagnosis. Titers of 1:40 were not considered as belonging to the positive group. The finding in so large a group of individuals, however, definitely show that this concept of diagnostic levels must be changed. Of our military personnel, 86 per cent gave reactions of 1:20 or less, making this titer the accepted limit of normal rather than the 1:40 and certainly not the 1:80. We present, therefore, for corroboration in the hands of other workers the serologic dilutions of 1:40 as being very suspicious of Scrub typhus, and level of 1:80 diagnostic of the disease. Whether these figures will hold for Classical typhus, we do *not* feel competent to discuss.

CONCLUSIONS

1. Using the Weil-Felix reaction as an index of immunologic status, 88 per cent of a group of military personnel immunized with the Cox classical typhus vaccine gave no response against the Proteus OX19.

2. Of this same group 80 per cent showed reactivity against Proteus OXK (the Scrub typhus strain).

3. Of the OXK reactions, 86 per cent were at a titer of 1:20, 1:10, or negative. From this we have concluded that a titer of 1:40 was very suspicious and 1:80 diagnostic of Scrub typhus.

4. The possibility is discussed of the vaccine employed being of a nature to incite immunity for Scrub typhus.

5. The problem of immunity against typhus requires additional immediate study relevant to cross reactions and specific protection afforded by vaccines.

Reference to literature other than that noted in the following bibliography was impossible due to our military situation.

We wish to thank the members of the Department of Bacteriology, under Lt. James B. O'Neill, for their assistance. The technical work was entirely done by Pfc. J. S. Carson and Pvt. R. D. Tuttle of this unit.

A RAPID AGGLUTINATION TEST TECHNIQUE*

Nathan Nagle, A.B., Lucille Schulze, B.S., and J. C. Willett, D.V.M.
St. Louis, Mo.

THE principle of shaking or agitation first applied practically by Kahn[1] in 1923 in his precipitation test for syphilis accounts to a large degree for the immediate results obtained by the Kahn test. Three minutes' shaking at a speed of 280 oscillations per minute with a stroke of 1½ inches (Kahn shaking machine) produces visible aggregations with beef heart lipoids (Kahn antigen) and syphilitic serum. Eagle[2] found that shaking shortened the time required for visible aggregation of antigen and specific antiserum. Visible aggregations were obtained with *Bacillus typhosus* and its antiserum in 4 minutes' and beef heart lipoids with syphilitic serum in 2 minutes' shaking. The speed or length of stroke of shaking is not stated.

The St. Louis Health Division Laboratories have used shaking in the agglutination test technique with bacterial antigens for the past several years. This practice was begun by C. L. Pfau, now deceased, but his data are not available. During the past two years sufficient data have been accumulated to show the usefulness of the method. The procedure developed in the rapid agglutination test technique for typhoid, tularemia, brucellosis, and other bacterial diseases is essentially adding 0.3 c.c. antigen suspension to 0.3 c.c. of serum dilutions, and agitating in a Kahn shaker for 6 minutes. A preliminary reading of the test is made and reported to the physician immediately if the titer is above 1:80. The test is then incubated for 5 hours at 37° C. in a water bath, after which time the final titer is reported.

Homologous antigens were added to positive sera in dilutions and agitated in a Kahn shaker for periods extending from 2 to 10 minutes. The maximum readings in the majority of sera were obtained after the 6-minute intervals. Table I shows the results with 20 sera with readings made at 2 minute intervals up to 10 and again after 5 and 18 hours' incubation at 37° C. Practically all of the sera developed their maximum titer after 5 hours' incubation.

One hundred and twenty-nine sera submitted for typhoid, tularemia, or brucellosis were tested with *B. typhosus* antigen, and readings were made after 6 minutes' shaking, 5 and 18 hours' incubation at 37° C. All sera submitted for an agglutination test are examined routinely for all three of these diseases. In a similar manner 131 sera were tested with *Bacillus tularensis,* 133 with *Brucella abortus* and 56 with *Bacillus proteus X19* antigens. Tables II, III, and V indicate the maximum titers of sera tested with *B. typhosus, B. tularensis,* and *B. proteus X19* antigens after 5 hours' incubation at 37° C. following the preliminary 6-minute shaking period. The incubation period for *Br. abortus* must be extended beyond 5 hours to obtain the maximum titer in a small percentage of sera as shown in Table IV.

*The St. Louis Health Division Laboratories.
Received for publication, June 8, 1943.

On a small number of known positive sera the rapid agglutination test method was compared with the technique described by the Standard Methods Committee of the American Public Health Association.[3] The essential differences between the two methods are shaking and length of incubation period. The A.P.H.A. method calls for 42 hours' incubation at 37° C. for *Br. abortus*,

The agglutination tests recorded in Table VI for *B. typhosus* and *Br. abortus* done by the A.P.H.A. method were also read after 6 minutes' incubation at room temperature, and again after 1, 2, and 5 hours at either 52° C. or 37° C. Visible aggregations were not observed after the 6-minute period although a small number showed aggregations in low dilutions after 1-hour incubation. The low titers obtained after 5 hours' incubation showed that long incubation periods are necessary in order to obtain the maximum titer when the antigen-serum mixtures are not shaken. Duplicate tests done by the rapid method were also read after 6 minutes' shaking and again after 1, 2, and 3 hours' incubation in the water bath at the appropriate temperature. Immediate reactions in low dilutions following the 6-minute shaking period were obtained with practically all sera recorded in Table VI. Higher titers were obtained after 3 hours' incubation, although it was necessary to incubate an additional 2 hours to obtain the maximum titer.

Antigen preparation in this laboratory follows the A.P.H.A. method very closely except that for Brucella antigen, formalin is used instead of phenol and the turbidity is 500 parts per million instead of 200 parts per million. The cul-

tures used are those distributed by the National Institute of Health including *B. typhosus* "O" and "H," *B. tularensis, Br. abortus,* and *B. proteus.* Sera submitted for Typhus or Rocky Mountain Spotted Fever are first examined with a *B. proteus X19* culture composed of both motile and nonmotile organisms made into a 0.3 per cent formolized suspension with a turbidity of 500 parts per million. Sera showing at least a 1:40 titer are repeated with live culture antigens made from *B. proteus OX19* and *OX2.* Table VI shows that the formolized and live culture antigens are equally sensitive.

CONCLUSIONS

The inclusion of shaking in the usual agglutination test technique enables the laboratory to secure comparatively rapid results. Six minutes' agitation in a Kahn shaking machine of the antigen-serum mixtures permits preliminary positive results to be reported at once, and following 5 hours' incubation at 37° C., the final titer can be reported.

CRITERIA FOR THE SELECTION OF AN ELECTROENCEPHALOGRAPH*

Louis W. Max, Ph.D.,† Leo Wiesner, Ph.D.,‡ and
Jesse G. M. Bullowa, M.D.,§
New York, N. Y.

The history of electrophysiology has repeatedly shown that experimental results may be distorted by the physical limitations of the recording instruments. This danger is especially marked in the comparatively new field of electroencephalography, where standardization of apparatus and procedure has not kept pace with the pressure for clinical applications. Accordingly, the relative advantages and disadvantages of available electroencephalographs merit careful scrutiny, since an error in judgment at the time of procurement may result in erroneous experimental and clinical conclusions.

Physical factors determining the accuracy of instruments for physiologic work and illustrations of errors introduced by inferior recorders have already been dealt with at some length by one of us:[1] the present report applies the earlier discussion to the selection of an adequate brain wave recorder.

ESSENTIAL REQUIREMENTS

1. *Constant Frequency Response.*—Among the requirements an electroencephalograph must fulfill in order to record an accurate picture of the brain potentials is constant frequency response. This means that individual brain waves of equal voltage even though of different frequencies must appear in the record as equal in height or amplitude. If the instrument cannot record the voltage of different frequencies with equal fidelity, certain waves of clinically significant frequencies may be discriminated against and escape detection.

2. *Linearity of Voltage Response.*—Another important requirement is linearity of amplitude response. The height of the pen deflections must be directly proportional to the magnitude of the brain potentials. For satisfactory recording and proportionality, this should hold within 5 per cent for pen displacements up to 7.5 millimeters on either side of the zero line.

Testing Apparatus: The following apparatus arrangement (Fig. 1) was employed to check upon the accuracy of frequency and amplitude re-

sponses of three commercial varieties of electroencephalograph. An electronic oscillator generates electrical waves of variable frequency; these waves are impressed upon a calibrated attenuator which adjusts their voltage to an appropriate value; these measured waves are, in turn, supplied simultaneously to the several channels of the electroencephalograph under test (EEG) and to an Einthoven electrocardiograph (ECG). The latter provides an independent, photographic check on the wave form, frequency, and amplitude of the test waves. The Einthoven galvanometer was adjusted to a constant frequency response from 0 to 100 cycles per second (c.p.s.).

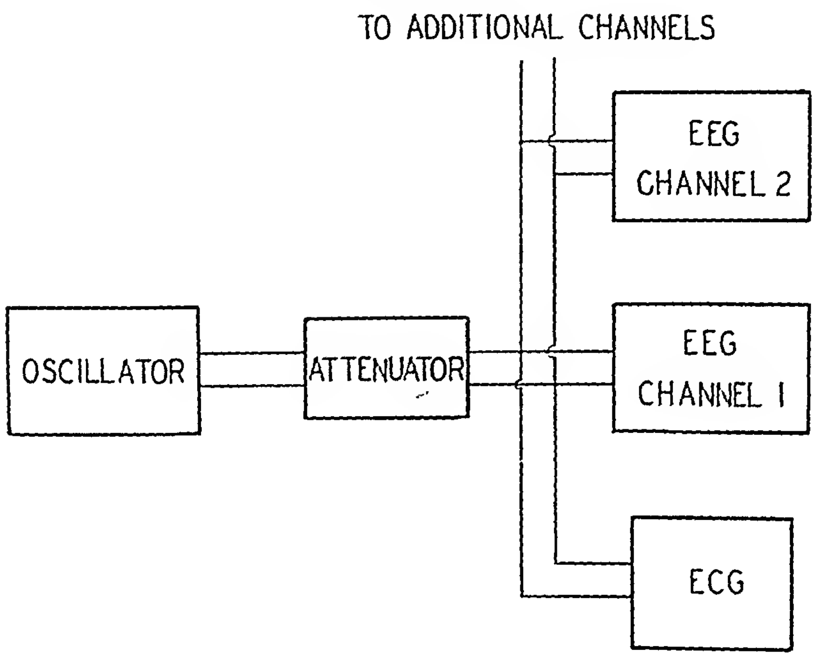

Fig. 1.

Fig. 2 presents the results of the above test on the three varieties of electroencephalographs tested. The curves present, in millimeters, the responses of the recording pens to electrical waves constant in amplitude but varying in frequency from 1 to 100 c.p.s.

It will be noted that while none of the recorders has a flat response in the entire range, the curves from two of the recorders, designated A and B, are markedly irregular in the range from 1 to 10 cycles, a range of frequencies of marked clinical importance. All of the curves are relatively flat in the range from 10 to 20 cycles, but instrument A showed an undesirable resonance peak at 25 cycles. Since this peak is well within the range of the physiologic frequencies to be recorded, serious frequency distortion would result.

In amplitude response, none of the models proved precisely linear, but the irregularities were not as important as in the case of the frequency response. Even the best of the three recorders deviated from strict linearity by a maximum of 13 per cent ($\pm$ 6.5 per cent).

3. *Freedom From Temperature and Humidity Effects.*—It is important that variations of temperature and humidity encountered in the average

laboratory shall not interfere with the stability of the recorder's operating characteristics. One of the instruments tested, model B, showed varying frequency and amplitude responses on different days; these, we discovered, were a function of its proximity to a warm radiator. This model was tested on a rolling laboratory table, and its stability of response depended on its distance from the radiator. Model A was free of this temperature effect, but its writing pens failed to maintain a constant zero position on moist days. Model C remained unaffected by such temperature and humidity variations.

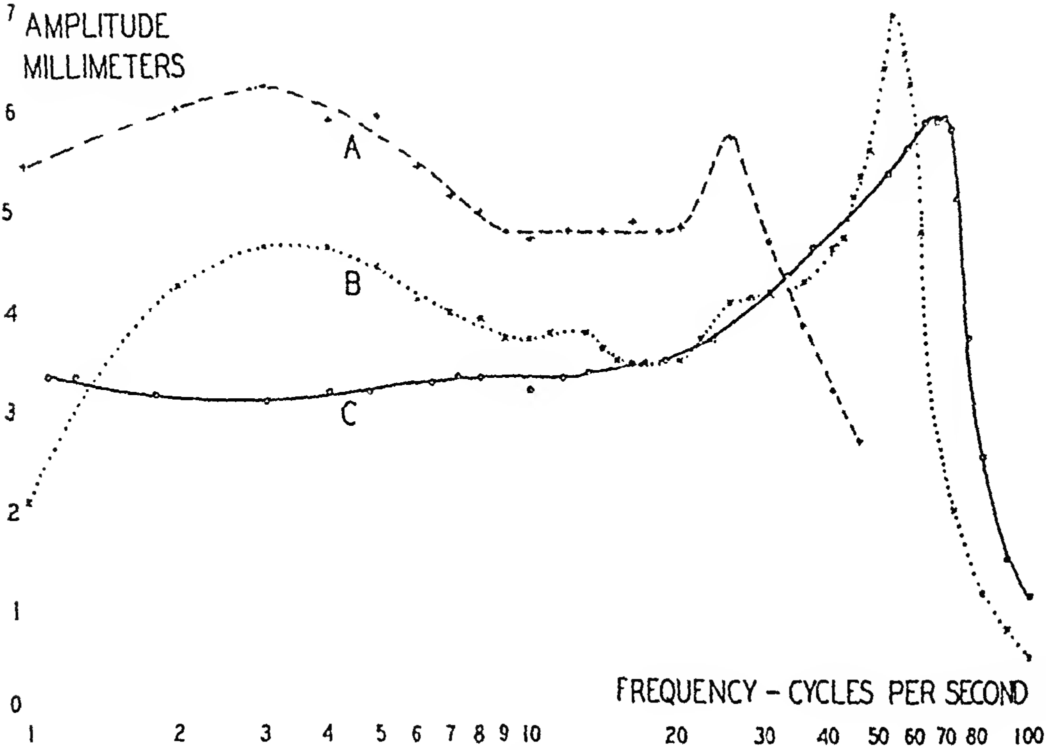

Fig. 2.

The following requirements seemed to be adequately met by all three of the models studied:

4. *Identity of Component Channels.*—Where, as is usually the case, a multiple channel electroencephalograph is to be purchased, the channels must be adjustable so that identical input voltages will produce identical records on all channels. This is important because it is sometimes desirable to switch electrode leads from one channel to another in the course of an electroencephalographic examination. Hence, a multiple channel instrument should meet the following test: After all the channels have been adjusted to give equal pen deflections for equal input voltages, all the channel inputs are to be connected in parallel to the same two electrodes on the patient's skull and simultaneous tracings taken. The tracings may then be superimposed on each other and no two of them should differ by more than ±5 per cent. If the amplifiers or recording pens are not well matched, the instrument will not pass this test.

5. *Freedom From "Cross Talk."*—One channel must not interfere with or influence the others. Such interference, termed "cross talk" by analogy with a similar disturbance in telephone and radio communication, makes the records worthless.

One way to check this is to connect one channel to the patient's skull; connect the inputs of the remaining channels to a noninductive 5000 ohm resistor and adjust them for maximum amplification. No component of the brain wave record of the first channel should appear in the other channels.

6. *Low Noise Level.*—Where no voltage is applied to the input of the electroencephalograph, one would expect a zero deflection or straight line to be recorded. Actually the line will probably contain some slight fluctuations termed "noise." Since brain waves of an amplitude lower than these random fluctuations cannot be detected, the "noise level" should be as low as possible and should not in any event exceed 2 microvolts. To check this, connect the inputs of all the channels to a noninductive 5000 ohm resistor (to simulate the patient's resistance); adjust the amplifiers for maximum gain and inscribe a record. As estimated from the microvolt calibration, the noise fluctuation should remain below the two microvolt level. This is particularly important for instruments containing B batteries, since the adventitious noise will increase as the batteries age and will later prevent satisfactory recording.

In view of the optimistic claims of manufacturers, purchase orders for an electroencephalograph should include definite specifications in accordance with the above requirements.

SUMMARY

Criteria for the adequacy of an electroencephalograph are described, and tests are suggested for checking its performance. Frequency response curves of three commercial instruments are presented.

SOME EXPERIMENTS ON THE ROMANOVSKY STAINING OF BLOOD FILMS

R. D. LILLIE, M.D.,* BETHESDA, MD.

IN the course of testing samples of Wright and Giemsa stains, it became necessary to arrive at a technique which would give the best tinctorial results of which the sample was capable, regardless of time or of convenience of the method, and these experiments led to results which appear to be of general practical interest.

Controlled experiments were used, using several samples of dye, varied staining times, and varied delutions. As test objects thin blood films from white rats heavily infected with *Trypanosoma equiperdum* were used. These were fixed as soon as dry in absolute methanol for 2 minutes. A phosphate buffer of pH 6.5 was used throughout, as this gives a good orange-pink color to erythrocytes and satisfactory blue cytoplasm to lymphocytes. The stock buffer contained 6.2 Gm. KH_2PO_4 and 3.0 Gm. Na_2HPO_4 in 500 c.c. each of CP methanol and distilled water and was diluted 1:20 with distilled water for use.

In the first experiment 1/2 and 1/3 dilutions of Wright stains LWr-17 and NWr-18 were used for 1, 2, 4, 7.5, and 15 minutes; 1/5 dilution for 2, 4, 7.5, 15, and 30 minutes; 1/10 for 4, 7.5, 15, 30, and 60 minutes; 1/20 and 1/32 for 7.5, 15, 30, 60, and 120 minutes, and 1/50 for 15 and 30 minutes, 1, 2, and 4 hours. The dilutions were made in test tubes and thoroughly mixed, as this procedure was found to give more uniform staining throughout the smear than the traditional method of mixing on the slide.

The 1/2 dilution, that is, one part of methanol stain solution and one of buffered water, gave fair staining of nuclei in blue to violet tints in 4 to 15 minutes, but the desired reddish purple chromatin staining was not attained. This coloration appeared first with the 1/3 dilution in 4 to 15 minutes, best at 7.5, rather dark in 15, but was best with the 1/5 and 1/10 dilutions in 7.5 to 30 and 15 to 60 minutes respectively. Satisfactory staining was still attained with the 1/20 dilution in 1 and 2 hours, but with higher dilutions did not occur even in 4 hours. The optimal dilutions and times of those tried were 1/5 for 15 minutes and 1/10 for 30 minutes.

Next, a similar series of stains was made with two samples of Giemsa stain, NGe-13 and NIH-2B, using 6 adjacent time intervals out of the following series: 2, 4, 7.5, 15, 30 minutes, 1, 2, 4, and 6 hours, for each dilution. The dilutions used were 1/10, 1/17, 1/25, 1/36, 1/50, 1/75, and 1/100. The two samples gave fairly similar results, with a slight but consistent difference in favor of the second. Optimal staining gave deep red purple leucocyte and lymphocyte nuclei, clear medium blue or slightly greenish blue cytoplasm of lymphocytes and trypanosomes, and sharply stained trophonuclei, blepharoplasts, and un-

Received for publication, June 17, 1943.

dulating membranes. It was noted in this and all subsequent experiments that when trypanosome staining was optimal, lymphocytes were somewhat overstained, while with optimal lymphocyte staining undulating membranes were often indistinct.

Times required for optimal staining with the various dilutions were as follows: 1/10, 15 to 60 minutes; 1/17, 1/25, and 1/36, 30 to 60 minutes; 1/50 and 1/75, 1 to 2 hours; and 1/100, 2 to 4 hours.

Following our experience with the acceleration of azure eosinate staining of tissues with acetone,[1] it was determined to apply this method to Giemsa staining of blood films. Accordingly, eleven 40 c.c. quantities of 1:50 dilution buffered to pH 6.5 were made up, using Giemsa stain NIH-2B and containing 0 to 10 c.c. acetone by 1 c.c. steps. Five staining intervals were used with each mixture, spaced so that each successive interval was approximately twice as long as the previous one.

Good but not quite optimal staining was attained in one hour without acetone. Optimal staining was attained in one hour with 1 c.c. acetone, in 30 minutes with 2 or 3 c.c. acetone, in 15 minutes with 3 or 4 c.c. acetone; good but suboptimal staining in 30 minutes with 5 or 6 c.c. acetone; inferior staining in any interval with 7 or 8 c.c., and very poor with 9 or 10 c.c.

As 3 c.c. acetone to 40 c.c. dilute stain seemed to be about the optimal quantity, it was decided to determine the effect of various dilutions of stock Giemsa NIH-2B for various time intervals, with and without acetone.

Five dilutions were used: 0.8 c.c., 1.0, 1.2, 1.4, and 1.6 c.c. stock stain to a total of 40 c.c. diluted mixture, (ranging from 1/50 to 1/25 dilution), with and without 3 c.c. acetone in the mixture. Four time intervals were used, each double the preceding as before. Optimal staining times for the 5 dilutions without acetone were 1 to 2 hours for the first two dilutions, 30 to 60 minutes for the remaining three. With acetone, times were 30 to 60 minutes for the first 2 dilutions; 15 to 30 minutes for the next two; and 15 or less for the last. Similar results were attained on repetition of this test using Giemsa stains NIH-2B, NGe-13, and LGe-6 at 1/50 dilution without acetone and 1/25 with acetone. The acceleration of staining in favor of the latter was between 3 and 4 times.

As these tests indicated that more concentrated dilutions of Giemsa stain might give even faster staining, a further series of tests was made using 2, 2.5, 3, 3.5, and 4 c.c. Giemsa stain LGe-6, 3 c.c. acetone and water buffered to pH 6.5 to make 40 c.c. Time intervals used were 2.5, 5, 7.5, 10, 15, 20, and 30 minutes. Optimal staining of trypanosomes and blood cells was attained in 2.5 to 5 minutes with the 1/10 dilution, while about 10 to 15 minutes was needed with the weakest (1/20) dilution.

Repeating this experience on a limited number of unfixed thick and methanol-fixed thin human blood films containing *Plasmodium vivax*, stains comparable to those obtained in 30 to 60 minutes at 1:50 dilution without acetone were attained in 15 to 20 minutes at 1:25 with acetone, and in 5 minutes at 1/10 dilution. The Giemsa (N43) used in this test contained some relative surplus of methylene blue, so repetition of the test with three other samples, NIH-2A, LGe-6, and NGe-13, was done, using thick and thin films containing *Plasmodium malariae*. Again, acceptable staining of parasite chromatin was attained in 6 minutes in both thick and thin films with all three samples and with one in 4

minutes. The thick films were prepared in the morning and stained the same afternoon. It is noteworthy that of 21 thick films stained 2 to 16 minutes, none were lost, while of 4 control thick films stained 30 to 90 minutes in 1:50 Giemsa without acetone, only one had a small area left to look at on the slide.

In the course of these experiments it was noted that one series fixed with previously used methanol seemed to give slightly better staining than expected. Thinking that this might be due to the presence of some water in the used methanol, experiments were made using 100 per cent, 95 per cent, 90 per cent, 85 per cent, 80 per cent, 70 per cent, 60 per cent and 50 per cent methanol in distilled water. Two lots of Giemsa were used, NIH-2B and LGe-6, 1/50 dilution without acetone, and 1/25 with 3 c.c. acetone to 40 c.c. with the first, the latter only with the second.

The 50 per cent and 60 per cent methanol gave complete hemolysis. Much karyolysis also was evident with 50 per cent methanol, fairly good leucocyte and rather poor trypanosome staining with 60 per cent. With 70 per cent some red corpuscles were intact, others partly hemolyzed, and with 80 to 100 per cent methanol red corpuscles were well fixed. There was no appreciable difference in the minimum time required for optimal staining of lymphocytes, leucocytes, and trypanosomes with methanol percentages from 70 to 100 per cent. Prolonging the fixation interval in 90 to 100 per cent methanol from 2 to 10 minutes appeared to improve the staining somewhat.

The Giemsa stain NIH-2B, which was the one most used in these experiments and appeared to be equal to or better than the commercial samples, was made in our laboratory from methylene blue and eosin by the method recently reported.[2] The procedure is quoted as follows, since the original may not be available to hospital laboratories.

"Dissolve 10 gm. methylene blue of 85-88 percent dye content in 600 cc. distilled water. Add 6.8 cc. concentrated sulfuric acid (sp. gr. 1.835 to 1.84). Bring to a boil and add 2.5 gm. potassium bichromate dissolved in 25 cc. distilled water. Boil 20 minutes. Cool to 10° C. or lower (place in refrigerator over night). When cold add 17.5 gm. sodium bicarbonate slowly with frequent shaking. Then add a 5 percent solution of eosin Y of about 90 percent dye content and shake constantly until margin of fluid appears pale blue or bluish pink. About 205 cc. will be required and three-fourths of this can be added at once. Filter at once, preferably on vacuum funnel with hard paper. When fluid has been drawn through and surface begins to crack, add 100 cc. distilled water, let drain, and wash again with a second 100 cc. distilled water. Lay the (opened out) filter on a larger piece of filter paper or paper towel and dry overnight on warm plate or in incubator, at 37°C. The drying may be accelerated by using two 100 cc. portions of acetone or, preferably, 95 percent alcohol as washes after the second wash with water. Drying at 55° to 60° C. has been tried, and produces quite a little alteration of the thiazin dye; less if acetone or alcohol washes are used and the heating limited to 2 or 3 hours. This is the crude azure B eosinate.

"To make the crude azure A eosinate, proceed exactly as above but take 5 gm. potassium bichromate in place of 2.5 gm. and dissolve it in 50 cc. distilled water.

"To make the methylene blue eosinate, dissolve 10 gm. methylene blue in

600 cc. cold distilled water and precipitate as before with 5 percent eosin, filtering and drying as above."

"To make the finished stain, grind the three eosinates separately into fine powder in separate clean mortars. (The same mortar may be used if washed out with water, dried with a paper towel, washed with concentrated sulfuric acid until no more green color is liberated, then again with water and alcohol.) Then weigh out 500 mg. crude azure B eosinate, 100 mg. crude azure A eosinate, 400 mg. methylene blue eosinate, and 200 mg. finely ground methylene blue. Decant the mixed powder onto the surface of 200 cc. of solvent allowing it to settle in gradually. Then shake frequently for 2 or 3 days, keeping the bottle between 50° and 60° C. between shakings.

"The traditional solvent is equal parts of glycerin and methyl alcohol. If the bottle is tightly stoppered and the fluid level marked on the outside with a grease pencil or a piece of adhesive, there will be little or no loss from evaporation, and in any case the fluid level can be restored by addition of methyl alcohol. The glycerin should be neutral, anhydrous, and of the purest grade obtainable. If the special methyl alcohol for blood work is unobtainable, ordinary C.P. methonal may be repurified by distillation in glass after adding 4-5 gm. each of silver nitrate and sodium hydroxide. This destroys aldehydes and anchors volatile acids as sodium salts."

CONCLUSIONS

Wright stain solutions made up in methanol in the usual 125 mg. per 100 c.c. proportions can be made to give blood and parasite stains comparable in color effects to Giemsa by increasing the dilution to 1/5 to 1/10 and prolonging the staining interval to 15 to 30 minutes.

Previous fixation in 80 to 100 per cent methanol and staining with premixed dilutions of either Wright or Giemsa stain is the preferable procedure. This indicates that methanol may be used repeatedly for fixation, as long as no evident hemolysis is produced.

Addition of 5 to 10 per cent acetone, best 7.5 or 3 c.c. to 40, decreases the time required for Giemsa staining to about half. Increase in the concentration of Giemsa stain in the final staining mixture decreases the required time proportionately so that with a 1:10 Giemsa stain dilution containing 7.5 per cent acetone excellent stains of thin blood films are obtained in 5 minutes, and thick films may be adequately stained in 5 to 6 minutes in the same mixture. Further, thick films may be stained promptly with much less danger of losing them when such short intervals are employed.

THE RECORDING OF LUNG CONTRACTIONS BY A PULLEY AND LEVER METHOD*

D. E. Jackson, M.D., Cincinnati, Ohio

A VARIETY of methods have been used by different investigators to study the reactions of the bronchioles to drugs, to electrical stimulation of nerves, blood pressure changes, air pressure variations, and other phenomena connected with the functions of the lungs and the respiratory air passages. The lungs and the air passages have such varied and extensive functions to perform that no single method could be expected to cover all phases of these phenomena. Earlier workers have placed a lobe of one lung in a plethysmograph (Brodie and Dixon, M. Cloetta) or have used a metal plate ("lung shield") in the chest to form a plethysmograph for one lung (Jackson), or a "lung plethysmograph" was placed inside the chest[1] to hold the walls in a relatively fixed position while the chest cavity was intermittently aspirated to carry on artificial respiration, the animal usually being pithed (Jackson). Another method involved the insertion of a cannula into the chest cavity, or the passage of a perforated tube transversely through the anterior portion of the chest wall, thus permitting air pressure changes from both pleural cavities to be recorded. More recently many workers have studied the reactions of small rings of isolated sections cut from the bronchioles. Sollmann and his co-workers have perfused isolated lungs through the trachea and noted the rate of outflow through perforations in the lungs. They have also used a special method to make microscopic cinematic studies of cross sections of fresh bronchioles.[2]

Most of these methods are too complicated or too time-consuming to be easily used by ordinary beginning medical students. Recently I have been using a method which I believe may be readily employed in ordinary class work.

Fig. 1 illustrates the apparatus and the technique which I have used. The animal (dog) is anesthetized and placed on the operating table. The chest is opened by a mid-line incision, the sternum being sawed through endwise, and four strong ligatures about eighteen inches long are passed through the edges of the opening in the chest and tied around the sawed edges of the sternum. These ligatures usually shut off the internal mammary arteries and veins and thus check any bleeding from cut branches of these vessels. At the upper end of the opening in the chest the mammary arteries should be examined and separated down to their origins, for in some animals these arteries branch off from a single stem. If this condition is found, then one of the arteries should be doubly ligated close to its origin and the artery should then be cut between the ligatures. The chest should now be pulled open about three or four inches and held in this position by tying the ligatures at the side of the dog board. If

*From the Department of Pharmacology of the University of Cincinnati College of Medicine.

Received for publication, September 9, 1943.

the chest is thus pulled open in an animal in which the mammary arteries come off from one stem, one of them may be torn off unless it has been tied and sectioned previously.

Positive artificial respiration is used, the lungs being well but not excessively inflated at the rate of about twenty-five or thirty times per minute (dog). The lungs and heart are freed from the membranous anterior mediastinum, and care is taken to see that all lobes move freely in the chest and over the heart. A string about four feet long which is as free as possible from stretch (a fishing line is very satisfactory) is now attached by a stitch to the tip of one lobe of the lungs. I have generally used the upper right lobe, but in some cases other lobes may be used to advantage.

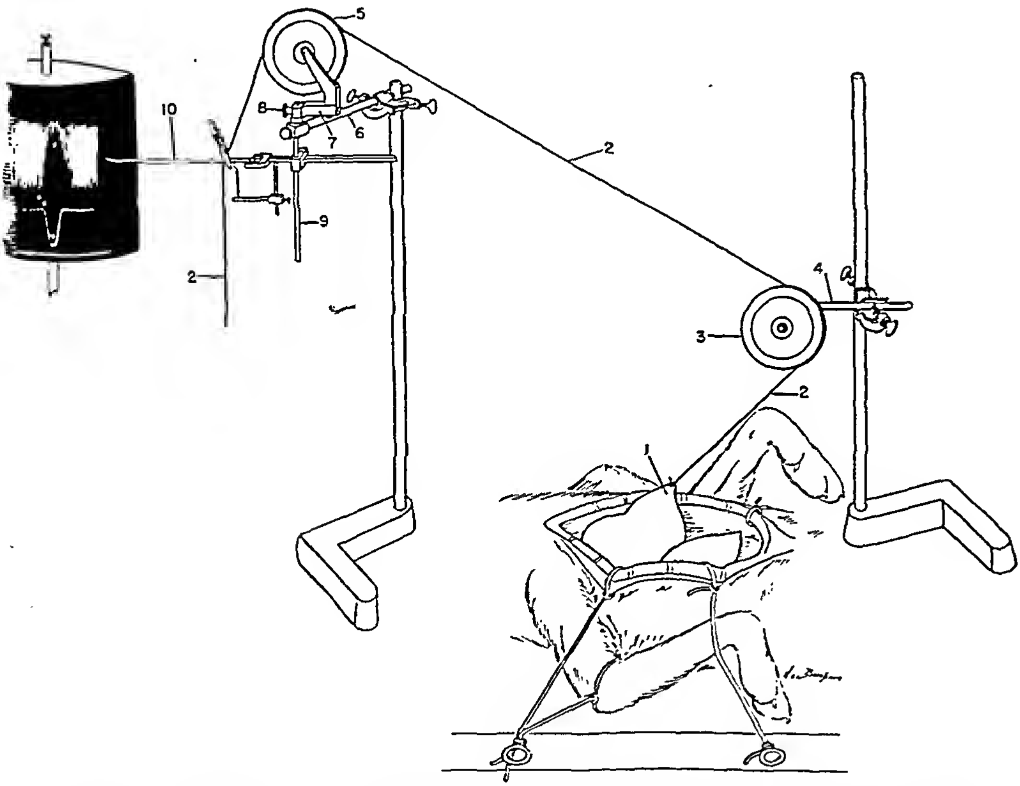

Fig. 1.—Diagrammatic representation of the lung apparatus and its method of application. For discussion, see text. (Apparatus made by the Max Wocher & Son Co., Cincinnati, Ohio.)

In Fig. 1 the string (*2*) is attached to the tip of the right upper lobe of the lung. The string passes over a pulley (*3*), four inches in diameter, and thence to the second pulley (*5*), also four inches in diameter. The distal end of the string is then clamped to the writing lever by a small, light bulldog clamp, which allows the string to be quickly and easily adjusted to give the desired magnification by the lever, or to make the lever write higher or lower on the drum. The two pulleys are made of light wood but have metal hubs which turn very freely on metal spindles. The pulleys are made large so that they can be turned very easily and thus not hamper the movements of the

lung lobe. The pulley *3* is supported by the rod *4*, which can be turned in the clamp on the stand. But the end of the rod *4* is bent at a right angle (behind the pulley *3*) and this short bent end turns in the metal block which carries the spindle supporting the pulley. This adjustment is secured by a setscrew in the metal block. By these two adjustments the pulley can be placed in any position and made to rotate in a plane which will direct the string toward the second pulley *5*, and also in such a position that the string attached to the lung can pull in the proper direction to record the movements most advantageously. The pulley *5* has some six different adjustments which are attained by the special arrangements shown in the parts *6*, *7*, *8*, and *9*. The writing lever (*10*) also has three adjustments, up and down (on the rod *9*), circularly (on the rod *9*), and back and forth (through the block and setscrew attached to rod *9*). The tension of the writing lever is partly regulated by a very fine, adjustable, coil spring and partly by the weight of the small bulldog clamp.

The writing point itself is made of thin aluminum foil so that it is light and very flexible. Since it moves at a rather rapid speed (25 to 30 double strokes per minute), it should be just stiff enough to maintain good contact with the surface of the drum. The up and down stroke on the drum should be about three and one-half to four inches (dog). It is essential that the whole mechanism works smoothly and with a minimum of friction. It is generally necessary, especially in the beginning, to do a little experimenting to find just the amount of weight and magnification to use for the lever. It can be seen that the device has a good number of adjustments. I have found that the proper adjustment is very necessary in order to get the optimum effects from the lung, and this is one of the most likely points for failure, even though the technique for the rest of the experiment has been entirely correct. At such a time I have repeatedly found that some slight readjustment of the apparatus may lead to complete success.

To obtain the best results, there will generally be two fundamental requirements which must be met. These are, first, a perfectly reliable artificial respiration machine, and, second, the animal must be kept still. Most laboratories now are equipped with respiration machines which are motor-driven and will regularly deliver constant quantities of air under constant pressure for each inspiration. An ordinary T-form of tracheal cannula is used, and the excess air delivered by the machine at each discharge is allowed to escape from the cannula through a short piece of rubber tubing which carries an adjusting (Hoffman's) screw clamp. In this manner the desired extent of lung inflation is easily secured.

Fig. 2 shows the effect which stimulation of the vagi nerves has on the lungs. Movements were recorded from the right upper lobe, but stimulation of either the right or the left vagus nerve in the cervical region caused a contraction. But the right vagus seems to be a little more effective than the left on the right lung lobe. Apparently the two vagi have so completely anastomosed before they pass into the lungs that either nerve can control either lung. This follows the embryologic development of the vagi along the gastrointestinal tract and the branching off of the lungs from the primitive gut. No doubt this is important clinically. There are some slight variations in the response of the lung to vagus stimulation, but these apparently follow very

closely the similar variations in cardiac response to the same stimulation. And the vagi endings in the lungs can be readily fatigued by stimulation just as occurs in the heart.

Fig. 2 also illustrates the marked increase in general tone of contraction of the lung lobe as shown by the whole tracing tending to rise above the normal level as the nerves are stimulated. This is also shown in another way in Fig. 4.

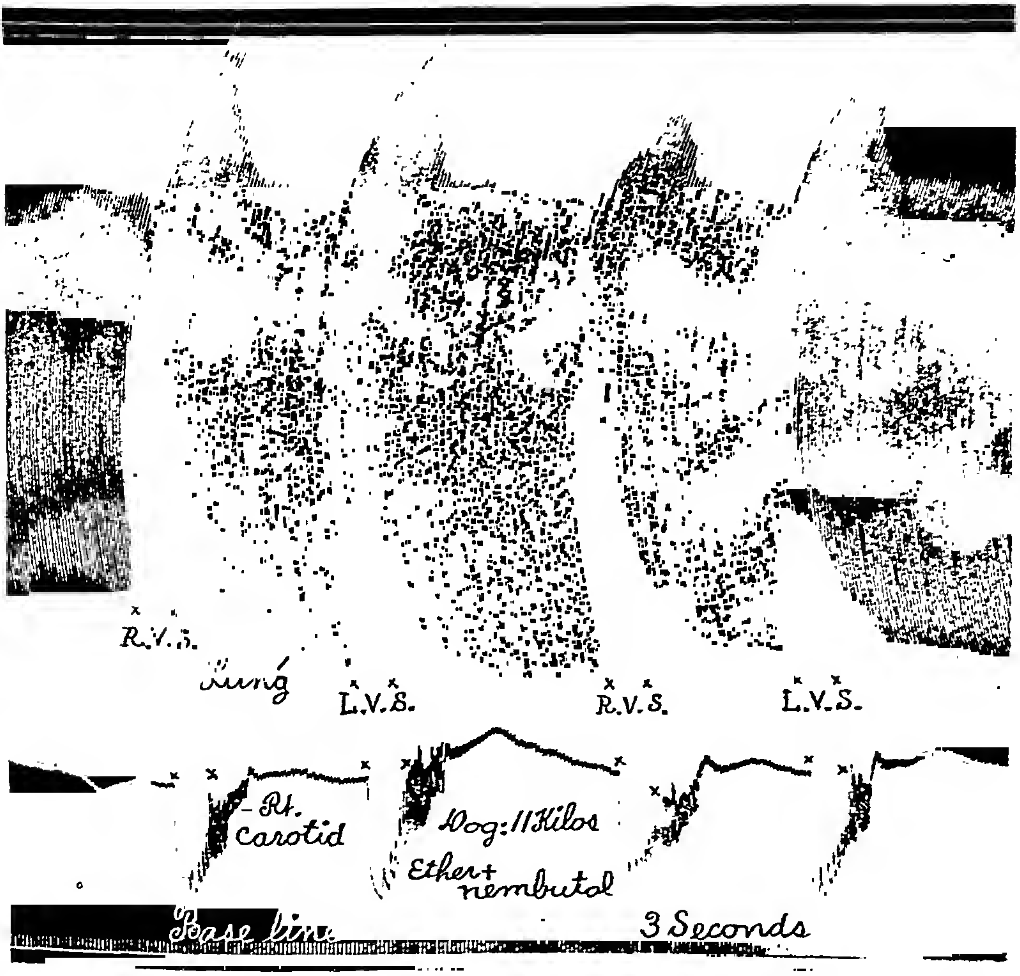

Fig. 2.—Lung tracing made from the upper lobe of the right lung, and the blood pressure recorded from the carotid artery. R. V. S., right vagus stimulated. L. V. S., left vagus stimulated.

The second basic requirement, that of keeping the animal still, may be attained in different ways. A drug of the curare type, or a large dose of nicotine, might be used. But in many cases these would be objectionable because of the ganglionic action which effective doses of these drugs may have. This might obscure or prevent entirely any central action which a drug injected later might have on the lungs. I have generally succeeded very well in keeping the animal quiet by giving ether only until all operative procedures

were completed, and then I have injected intravenously one or more cubic centimeters of nembutal solution (Abbott's solution). This is done slowly and cautiously until just the right depth of anesthesia is obtained, and then a normal tracing is taken and the drug to be studied is injected, or such other procedures as have been planned are carried out. In a certain number of instances some disturbances of the records may occur, because a profound bronchoconstriction or a great fall in blood pressure may lead to such a marked degree of asphyxia that this leads to central stimulation and may

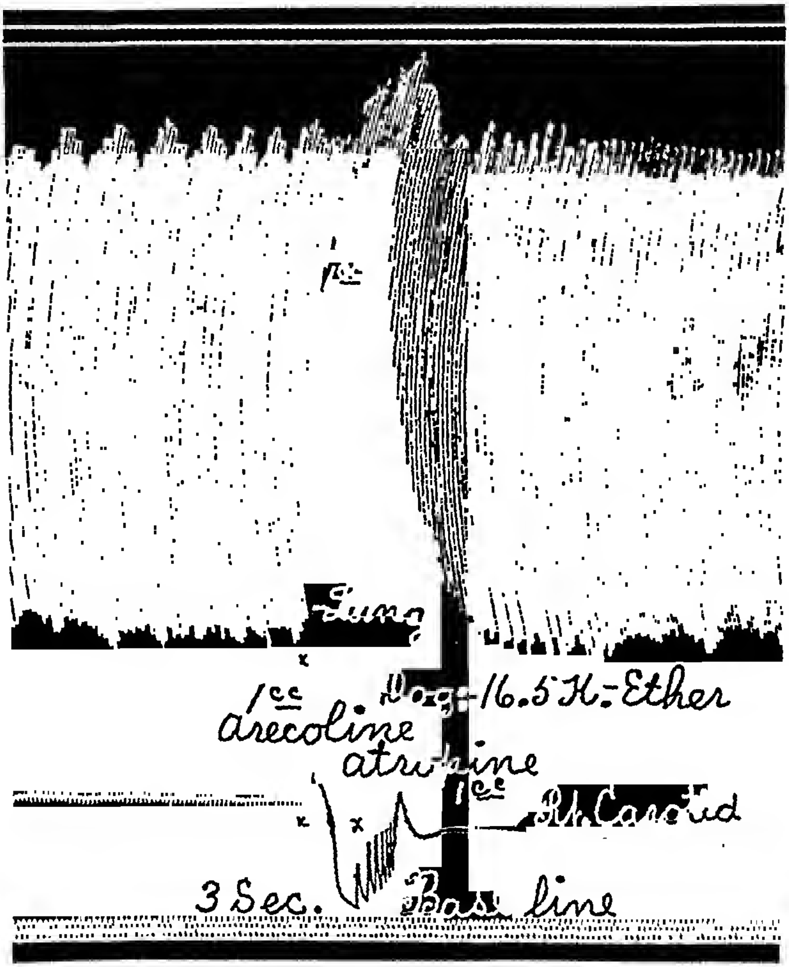

Fig. 3.—Lung tracing and blood pressure showing the action of arecoline followed by atropine. These well-known drugs are used so that the results may be compared with those obtained by other methods.

cause the animal to make special attempts to breathe deeply, or other convulsions or squirming movements may occur. A sufficient dose of nembutal may control these movements, but in some cases this may cause too great a weakness of the heart or too great a fall in the blood pressure. Such difficulties can usually be overcome by injecting smaller doses of the bronchoconstricting drugs. Possibly section of the nerves to the carotid sinuses and bodies might help in some cases.

Fig. 3 illustrates the action of two common drugs, areeoline and atropine, on the lung and on the blood pressure. There is a certain differenee in form between this tracing and one made by a plethysmographic method. In the latter ease the narrowest part of the lung traeing is usually near the middle of the up and down stroke of the lung tambour, and a general inerease in tone of the whole lung musculature can hardly be seen in the plethysmographic tracing. But with this pulley and lever method even a slight increase in general muscular tone can be seen, even though there may be no apparent constriction of the bronchioles as this is usually interpreted in plethysmographic

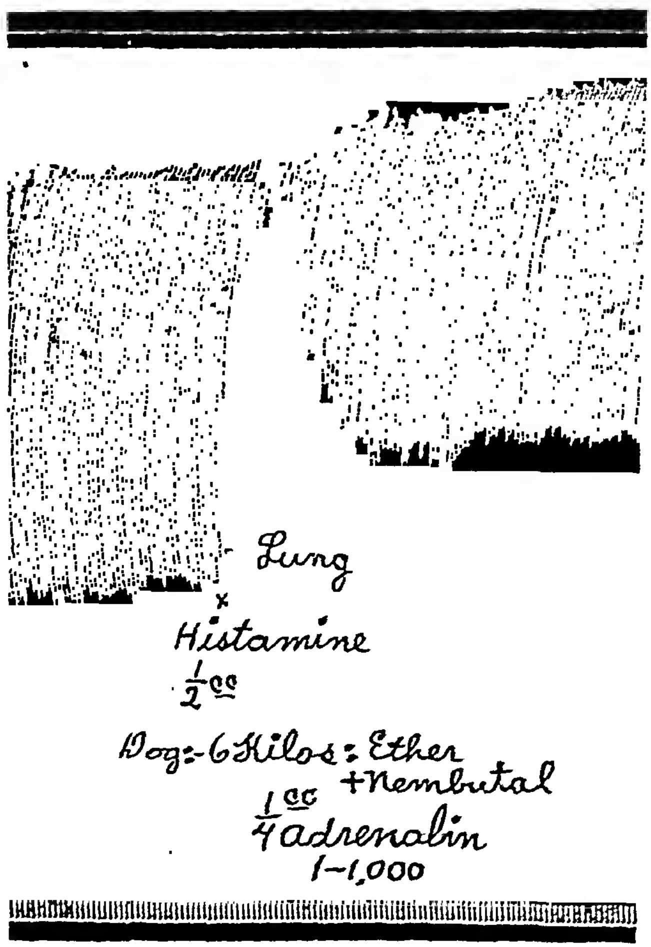

Fig. 4.—Lung tracing showing the action of histamine and adrenalin. Note increased tone (general rise of record) after histamine, even though adrenalin causes partial bronchodilatation.

tracings. A general upward shifting of the whole lung tracing as made by the pulley and lever method means an increase in tone of the whole lung musculature. Probably in the plethysmographic record the changes recorded are due mainly to alterations of the lung musculature in the transverse diameter of the lung lobes, but in the pulley and lever method the changes are obviously mainly in the longitudinal diameter of the lobe.

It can be noted that the upper limit of the left-hand portion of the lung tracing in Fig. 3 shows a kind of saw-tooth effect. This appears to be due to a peristaltic-like waxing and waning of the tone of the lung muscles. While a regular periodic variation in the force with which the air is delivered by the artificial respiration machine might produce such a variation, still as a result of many observations I believe that these effects are generally due to changes occurring within the lungs themselves, or possibly in some instances, due to changes in the pulmonary circulation brought about by variations in the efficiency of the heart.

It is advisable that the air blown into the trachea to inflate the lungs should not be introduced as a sudden strong blast. This may be avoided by passing the air through some closed vessel holding a gallon or more, just before the air is blown into the tracheal cannula. I have frequently used a five-pound ether can for this purpose. Two five-eighth inch tubulatures about one inch long were soldered into the can, one in each end, and this was placed in series with the rubber respiration tube near to the tracheal cannula. The can thus serves as a buffer to tone down a blast of air that may be too strong.

Fig. 4 shows the action of histamine and adrenalin on the lung. It will be noted that the adrenalin partly but not completely overcame the muscular constriction caused by the histamine. The persistent action of the histamine is shown by the gradual rise of the whole tracing, even after the adrenalin has produced a considerable dilatation of the bronchioles. It may be that this progressive increase in tone is due to an action on longitudinal muscle fibers running in the lung lobe more than to an effect on the circular fibers which run in the walls of the bronchioles.

SUMMARY

A simple, practical method for recording lung contractions is presented, together with some results obtained by nerve stimulation and the administration of some common drugs. This method may be useful in ordinary class experiments. It keeps the normal innervation and circulation of the lungs intact.

A NEW FORM OF MYOCARDIOGRAPH TOGETHER WITH THE TECHNIQUE NECESSARY FOR ITS USE*

D. E. JACKSON, PH.D., M.D., CINCINNATI, OHIO

A VARIETY of special devices for recording contractions of the heart have been used by many investigators in the past.[1] Each of these devices has generally been designed with the object of overcoming one or more of the special difficulties involved in the nature of the experiment. Perhaps the most disturbing feature in the average experiment is the constant up and down or wavering movement which the heart assumes as a result of the inflation and deflation of the lungs by the artificial respiration machine when the chest is opened. The device shown in Fig. 1 has been designed to reduce this disturbance to a minimum. Since the device consists of two parts, the only connection between which is the string (*6*), it is easy to place each part in the most convenient position on the operating table. The writing lever and its mountings may be placed near the drum and at such an angle as will render the recording most efficient.

The experiment is performed by opening the chest of the anesthetized animal by a median longitudinal incision, the sternum being sawed through endwise, after which the chest is opened laterally about three or four inches (dog) and secured in that position by the ligatures which are tied at the sides of the operating board. Care should be taken not to rupture one of the internal mammary arteries in case both should arise from a single stem. The pericardium is opened by a median longitudinal incision, and each side of the membrane is attached up to the chest wall by a single stitch. The pericardium thus forms a kind of hammock in which the heart rests. Care must be taken to see that the heart or the incoming large veins, particularly the inferior vena cava, are not closed off or obstructed by any pull on the pericardium. It may frequently be desirable to make one or more incisions in the cut edges of the pericardium so that the heart may be permitted to beat freely and without any obstruction whatever. The stand carrying the heart levers is now brought near the edge of the operating board and so adjusted that the short levers (*2*) and (*3*) can be placed just over the heart (*1*), the levers being so oriented that their movements will be approximately in the same direction as the longitudinal axis of the heart. By means of the adjustment which is regulated by the setscrew (*5*) the levers are moved near together so that they may be sewed to the heart, each by a single stitch of a very strong thread. ("Button hole" thread is very satisfactory.) Thus the levers are left close together until the recording lever is brought up to the drum. Then, to match the other adjustments, the levers are moved farther apart again and fastened in place by the set screw (*5*). The purpose of this is to put the heart muscle on the proper tension between the attached levers. Oth-

erwise increase or decrease of tone in the heart would not be properly shown by the writing lever.

The string (*6*) should have as little stretch as possible. (A fishing line is very satisfactory.) This string passes through the small coil spring (*9*) over the pulley (*16*), two and one-half inches in diameter, to the pulley (*17*), four inches in diameter, and finally is attached by a bulldog clamp to the writing lever. The bulldog clamp permits ready adjustment of the string so that the lever can be made to write higher or lower on the drum or the magnification can be quickly changed. The spring (*9*) serves as a flexible hollow tube through

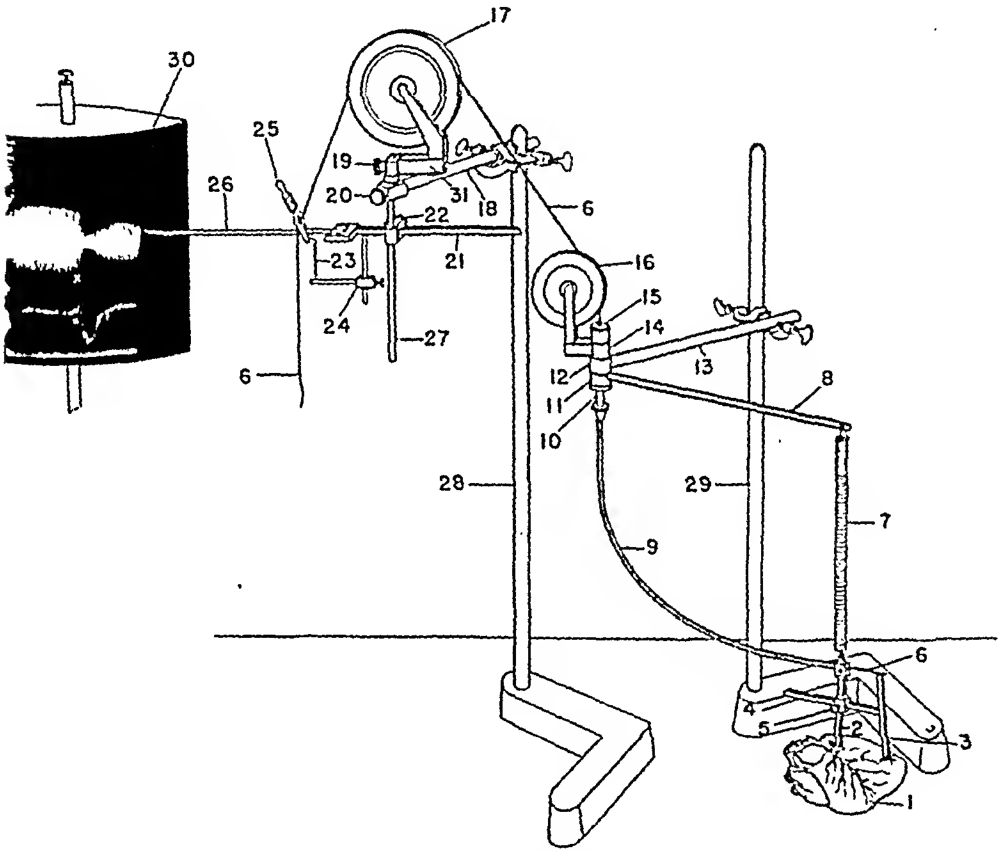

Fig. 1.—A diagrammatic representation of the myocardiograph and of its method of application. The distance between the two stands may be adjusted to suit the size and arrangement of the dog board or operating table, the position of the drum, etc., by simply extending or shortening the segment of the string *6* between the two pulleys. For discussion, see text. Device made by the Max Wocher & Son Company, Cincinnati, Ohio.

which the string slides freely. The spring is made of stiff steel or brass wire and is about one-fourth inch in diameter. The wire is wound closely, and the spring can be bent freely in any direction without changing the length of the enclosed segment of the string. It is this feature which permits the heart to be moved about by the lungs as they are inflated and deflated without these movements being recorded on the drum. The springs which I have used are sold in "dime" stores and are used to hold curtains back against window casings. The springs are cheap and very efficient.

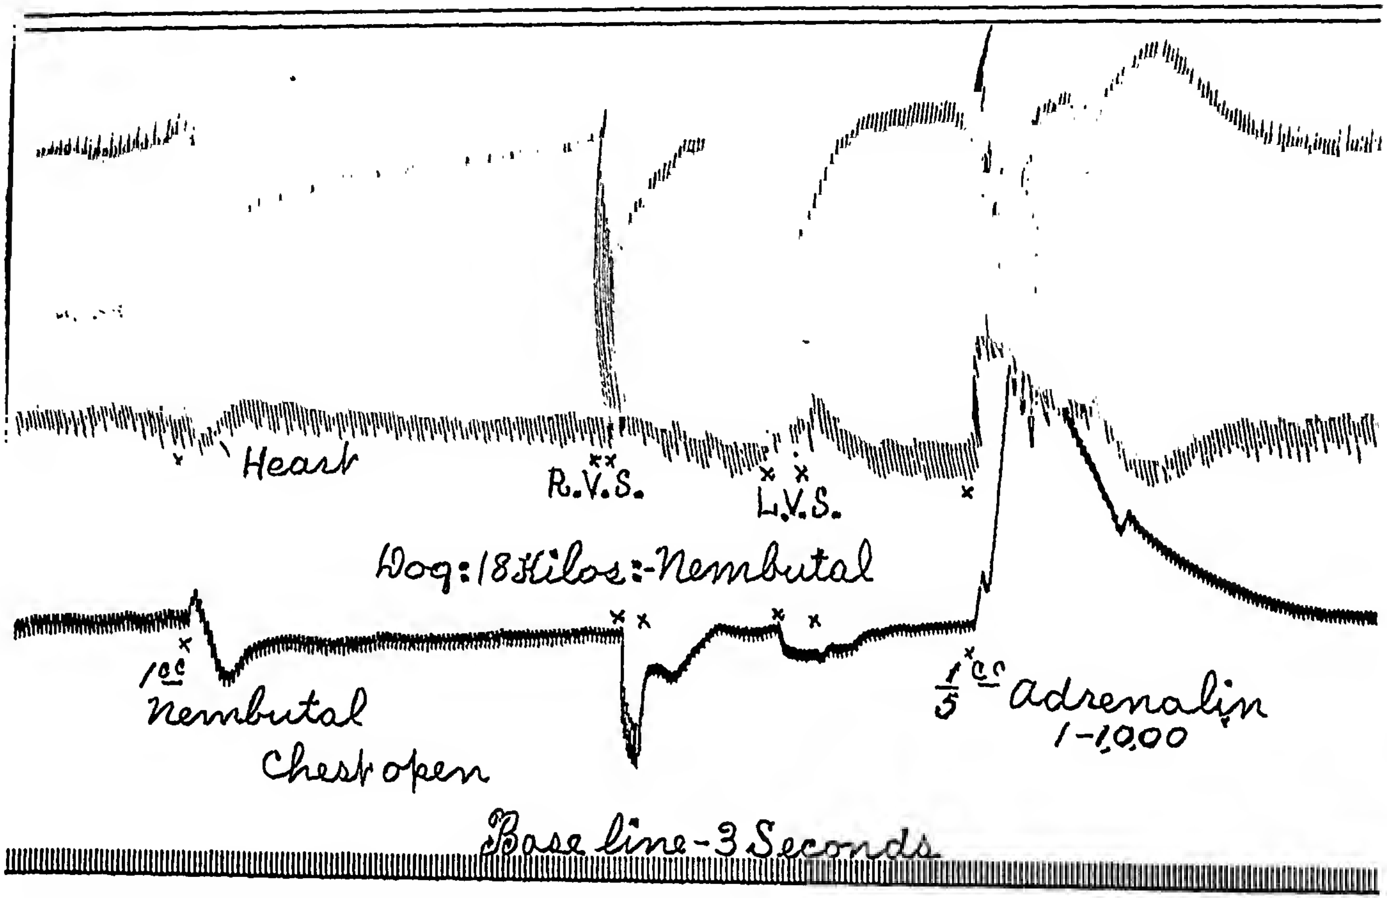

Fig. 2.—Myocardiogram and blood pressure tracing, showing the effects produced by nembutal, vagus stimulation, and injection of adrenalin. For discussion, see text.

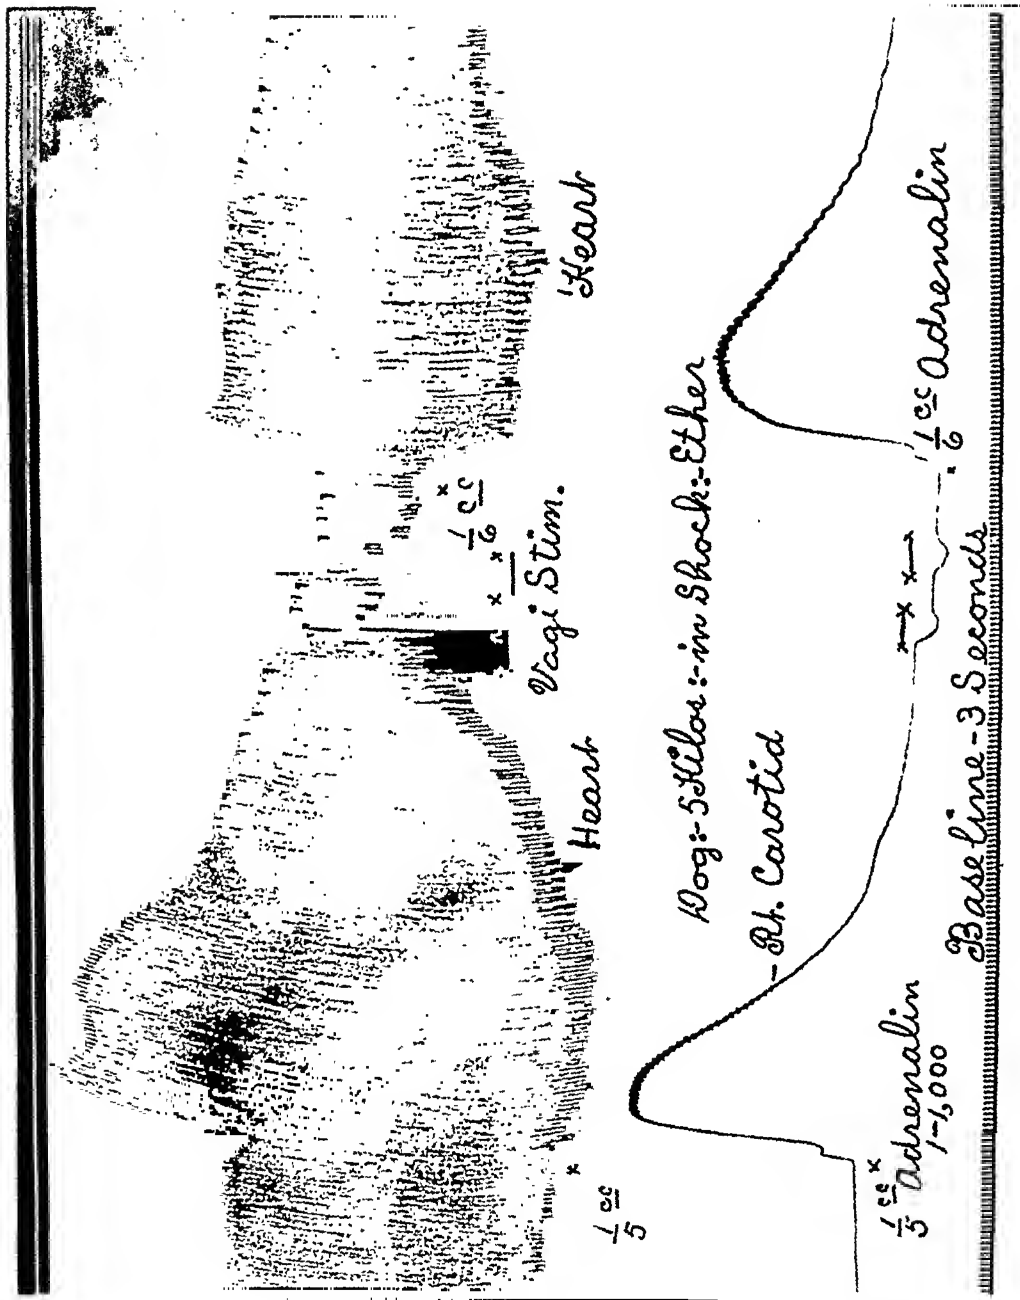

Fig. 3.—Myocardiogram and blood pressure recorded from a dog in deep shock. For discussion, see text.

The spring (*9*) is attached to the metal tube (*10*) which passes upward through the cylindrical parts *11, 12,* and *14.* The rod (*13*) is firmly fastened to the cylinder *12,* and rod *8* is attached to cylinder *11,* while the wood pulley (two and one-half inches in diameter) is attached to cylinder *14.* All of these parts can be firmly fixed in any desired position by merely tightening the nut *15,* which is threaded on to the upper end of tube *10.* The spring *7* supports the heart levers and holds them in position just above and barely touching the heart before they are stitched to the heart. This prevents the instrument from adding any extra strain on to the heart. The pulley *16* turns very freely on its axis,

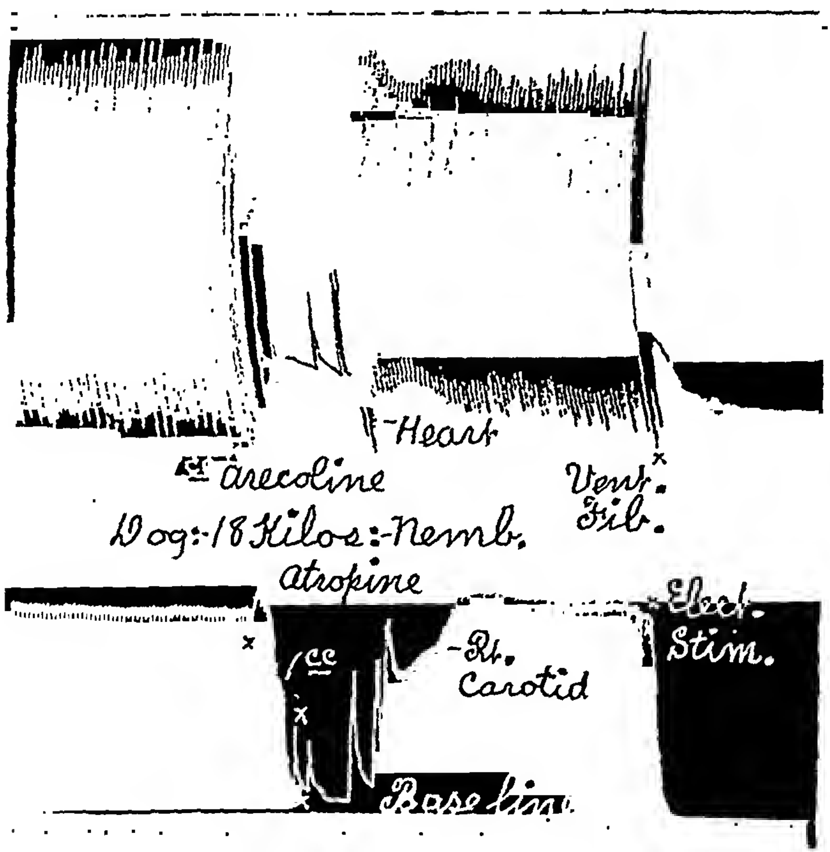

Fig. 4.—Myocardiogram and blood pressure tracing showing the action of arecoline and atropine and the development of ventricular fibrillation. For discussion, see text.

and it can be rotated on the tube *10,* so as to face the larger pulley (*17*) on the recording device. By means of the parts *18, 19, 20, 27,* and *31,* the pulley *17* (made of wood) can be adjusted in six different ways. The writing lever can also be independently adjusted up and down, back and forth, or circularly around the rod *27.* Tension on the writing lever (*26*) is regulated both by the weight of the bulldog clamp and by the coil spring *23* which can be adjusted by means of the setscrew and part *21.* Positive artificial respiration must be used with this machine.

Fig. 2 illustrates some common results recorded by this device. The blood pressure was recorded from the right carotid artery. Nembutal was injected, the right and left (intact) vagi nerves were stimulated, and adrenalin was injected intravenously. The right vagus was considerably more active than the left. It will be noticed that the excursions of the heart were actually considerably reduced when it was acting against the very greatly increased blood pressure caused by the adrenalin, but as the pressure fell, the excursions increased considerably. There is always some chance that a certain amount of "fling" may be recorded by the lever when the heart is beating very fast. The lever should be light and flexible. I have found that very thin spring steel is satisfactory, but perhaps aluminum of the proper thickness and temper might be better.

Fig. 3 shows the myocardiogram and blood pressure of a dog in shock. Two injections of adrenalin were given, and the vagi nerves were stimulated. The blood pressure was so low that the vagus inhibition hardly showed in the blood pressure record, but the effect is obvious in the myocardiogram. Also the brief period during which adrenalin is effective in shock is well shown.

It should not be forgotten that experiments of this character may show a number of points which are not revealed by electrocardiographic tracings, and in many instances observations in one field might well be used to supplement information obtained in the other.

It is sometimes surprising to note how much tension or counterweight must be put on the writing lever in order to secure the optimum contraction records from the heart. The heart tracings should generally be started with an amplitude of about two and one-half to three inches, but it not infrequently happens that a slight stimulation of the heart may cause the record quickly to reach an amplitude of five or more inches, or it may become so marked that the tracings cannot well be recorded on the available drum space. In these cases the height of the initial tracing should be reduced before the stimulating procedure is started. It is highly essential that all parts of the apparatus be properly adjusted before the record is started. A certain amount of experience, and in each case some trial and error, must be carried out in order to secure a maximum of success.

Fig. 4 shows the action of arecoline and atropine on the heart and blood pressure. At the end of the tracing the heart was stimulated directly with a Faradizing current and thrown into fibrillation. The myocardiogram shows the complete diastolic state into which the heart quickly passes as the ventricles begin to fibrillate and the blood pressure promptly falls to zero.

SUMMARY

A new form of myocardiograph is described. Tracings which are made with it and which show the action of some common drugs and of some laboratory procedures are presented, together with a discussion of the technique involved.

REFERENCE

1. Several methods and instruments for recording myocardiographic tracings are given in Jackson's "Experimental Pharmacology and Materia Medica," ed. 2, St. Louis 3, Mo., 1939, C. V. Mosby Co. Most of the operative technique needed for the use of the device described in this paper is given in detail in the above text.

CHEMICAL

THE QUANTITATIVE DETERMINATION OF COMBINED CHOLESTEROL IN THE PRESENCE OF BILE*

Francis F. Foldes, M.D.,† Boston, Mass.

In the course of some experiments it became necessary to determine the eventual combined cholesterol content of the bile of different animals. In looking for a suitable method we found two methods described: one by Wright[1] and the other by Riegel and Rose.[2] The method described by Riegel and Rose appeared to be too complicated for use in a clinical laboratory. The method described by Wright proved to be unsatisfactory in our hands. By adding known quantities of cholesterol esters (acetate propionate and palmitate) alone and mixed with cholesterol to bile, the results we obtained with the Wright method were inconsistent. In the presence of bile, digitonin failed to precipitate free cholesterol quantitatively; furthermore, neither free nor combined cholesterol could be extracted quantitatively with petroleum ether from the residue of the evaporated alcohol-ether extract.

By a simple modification of the method described by Lloyd[3] for the determination of total cholesterol, we were able to determine the combined cholesterol content of bile with satisfactory accuracy. Since the bile of the animals we tested did not contain ester cholesterol, we checked the method by adding known quantities of free and combined cholesterol, dissolved in alcohol, to bile.

METHOD

Bile was diluted ten times with distilled water. To 4 c.c. of this diluted bile, 20 c.c. of 95 per cent alcohol were added in a 50 c.c. Erlenmeyer flask. After mixing thoroughly and adding a piece of quartz to avoid bumping, the mixture was heated in a water bath between 70 and 80° C. for 5 minutes. After heating, the contents of the flask were filtered through a fat-free filter into another 50 c.c. Erlenmeyer flask. The filter was washed twice with 3 c.c. of warm alcohol. Following this, the filtrate was shaken for 2 minutes with 30 c.c. of petroleum ether in a separatory funnel. After the separation of the alcohol and petroleum ether layers, the alcohol layer was allowed to flow back into the flask which had contained the filtrate. The petroleum ether phase was then poured out of the top of the funnel. The last 1 to 2 c.c. of petroleum ether in which there was a small amount of alcohol containing bile was left behind and was subsequently added to the alcohol fraction in the Erlenmeyer

Received for publication, August 7, 1942.

flask through the stopcock. The procedure of extraction was repeated twice more. Because of the great solubility of bile salts and bile pigments in alcohol slightly (1:6) diluted with water and the equally great solubility of cholesterol in petroleum ether, after the third extraction all of the cholesterol was contained in the petroleum ether fraction and was collected in a 100 c.c. volumetric flask. All nonlipid bile constituents were contained in the greenish yellow alcohol fraction. The careful performance of the separation of the two fractions is essential for correct results, because the presence of even small amounts of bile in the petroleum ether fraction can be the cause of gross inaccuracies.

TABLE I

COMPARISON OF THE AMOUNT OF TOTAL AND COMBINED CHOLESTEROL DETERMINED AND CALCULATED

EXP. NO.		TOTAL CHOLESTEROL		COMBINED CHOLESTEROL	
		FOUND MG.	CALCULATED MG.	FOUND MG.	CALCULATED MG.
1.	4 c.c. palmitate solution*	0.35	---	0.22	---
	4 c.c. palmitate solution	0.34	0.35	0.23	0.22
	0.2 c.c. dog bile	0.24	---	0	---

	4 c.c. palmitate sol. and 0.2 c.c. dog bile	0.57	0.58	0.21	0.22
2.	4 c.c. palmitate solution*	0.35	---	0.23	---
	4 c.c. palmitate solution	0.34	0.35	0.23	0.22
	0.2 c.c. cat bile	0.17	---	0	---
	4 c.c. palmitate sol. and 0.2 c.c. cat bile	0.50	0.52	0.22	0.23
	4 c.c. palmitate sol. and 0.2 c.c. cat bile	0.51	0.52	0.21	0.23
3.	0.3 c.c. acetate solution*	1.07	---	0.98	---
	0.3 c.c. acetate sol.	1.09	1.07	0.94	0.98
	0.2 c.c. dog bile	0.25	---	0	---
	0.3 c.c. acetate sol. and 0.2 c.c. dog bile	1.30	1.32	0.96	0.98
	0.3 c.c. acetate sol. and 0.2 c.c. dog bile	1.29	1.32	0.95	0.98
4.	0.3 c.c. acetate solution*	1.07	---	1.03	---
	0.3 c.c. acetate solution	1.07	1.03	1.03	1.03
	0.2 c.c. rabbit bile	0.15	---	0	---
	0.3 c.c. acetate sol. and 0.2 c.c. rabbit bile	1.25	1.22	1.01	1.03
	0.3 c.c. acetate sol. and 0.2 c.c. rabbit bile	1.21	1.22	1.00	1.03

*Determinations marked were made according to Bloor and Knudson's[1] method.

After the separation is completed, the extract is made up with petroleum ether to 100 c.c. Fifty c.c. of this are set aside and are used for the determination of total cholesterol as described by Lloyd.[3] The other 50 c.c., used for the determination of combined cholesterol, are placed in a 50 c.c. beaker or Erlenmeyer flask. (The volumetric flask is washed out with 1 to 2 c.c. of petroleum ether twice.) After adding a piece of quartz to avoid bumping, it is evaporated gently on a steam bath under a hood. The evaporation of petroleum ether, previous to the addition of digitonin, is necessary, because digitonin does not quantitatively precipitate cholesterol dissolved in petroleum ether. The evaporation must be slow; otherwise a large part of the cholesterol

remains on the wall of the vessel. After the evaporation of petroleum ether, 12 to 15 c.c. of hot alcohol-ether mixture (3:1) are added, allowing this to run down slowly on the wall of the vessel, thereby washing down those cholesterol particles which have precipitated on the side of the vessel. To ensure quantitative results, the vessel is now heated on a water bath covered with watch glass for 5 minutes, after which the sides are washed down with 2 to 3 c.c. of ethyl ether. This done, 2 c.c. of a 0.5 per cent digitonin solution are added, and from then on the determination proceeds exactly as given by Bloor and Knudson.[4] In the colorimetric determinations a red filter was used as recommended by Bloor.[5]

RESULTS

To check the accuracy of the method, a known amount of alcoholic solution of a cholesterol and cholesterol palmitate mixture, or a similar amount of cholesterol and cholesterol acetate, was added to bile, the cholesterol content of which had been determined beforehand. Despite the low solubility of cholesterol and cholesterol esters in alcohol, alcoholic solutions were used to ensure complete extraction by the petroleum ether. The cholesterol content of bile and cholesterol mixtures was also determined, and the values found were compared with the ones expected. The results are shown in Table I. For brevity, the cholesterol and cholesterol palmitate and cholesterol and cholesterol acetate mixtures are listed in the table as palmitate and acetate solutions respectively.

SUMMARY

A simple method is described for the simultaneous determination of total and combined cholesterol in the presence of bile.

BOOK NOTICES

Indigestion, Its Diagnosis and Management, With Special Reference to Diet*

"INDIGESTION" is a word which mystifies physicians just as frequently as medical terms mystify the layman. Rehfuss says that to the layman indigestion represents "the vast category of conditions, both inside and outside the digestive tract, that makes him conscious of his digestion." It is this fact that makes "indigestion" so vague and hard to interpret, though to the patient it may be the outstanding symptom.

Rehfuss examines indigestion from the etiologic point of view, unraveling much of the confusion caused by the unfortunate nature of the word. Sample chapter heads in his book are as follows: "Nervous Indigestion," "Indigestion due to Allergy," "Indigestion Secondary to Infection," "Indigestion due to Gastric Functional Disturbances," "Biliary Tract Type of Indigestion," "The Indigestion of Cardiovascular Disease," "The Indigestion of Old Age." Each chapter considers the diagnosis and treatment of the special type of indigestion and its underlying cause.

Over 150 pages are devoted to the special place of diet in the treatment of gastrointestinal disease. This should be especially useful to the general practitioner, students, and others as a guide for proper management of food intake, which in all disease is of major concern to the patient.

Rehfuss writes in a light, anecdotal style, drawing freely from his own experience in gastroenterology for emphasis of important points. *Indigestion* can be recommended to all as a teaching book and as a reference book for the practical management of patients with gastrointestinal complaints.

Visual Mechanisms†

VISUAL mechanisms was the subject of one of a series of symposia arranged in celebration of the Fiftieth Anniversary of the University of Chicago in 1941. Problems of vision were discussed from the physical, biochemical, physiologic, anatomic, histologic, and psychological points of view. The present volume contains additional contributions which supplement the eight original papers.

The topics include the anatomy and function of the retina and visual cells, the neurophysiology of the optic pathway, the significance of the geniculostriate system, and the originization of the occipital lobe.

There are more general discussions of cerebral organization, energy relations in vision, and a theoretic consideration of sensory acuity.

Four subjects of special interest at the present time are the photochemistry of visual purple, vitamin A, the effect of anoxia on the visual system, and alpha waves in relation to structures involved in vision.

Visual Mechanisms was written by investigators in the advance guard of visual research today. It acts in no sense as a general text in vision. Its purpose is to give an account of the possibilities of the latest research methods.

Autonomic Regulations*

THIS book is a very complete review of the nervous and hormonal mechanism which maintains the constancy of the internal environment against the stresses upon the body from the outside. Emphasis is placed on the mutual relationships of the various organs and how changes in the external environment affect the various organ systems of the body. Adjustment reactions of the respiratory and circulatory systems to carbon dioxide, anoxia, asphyxia, hemorrhage, and hypoglycemia receive attention in the first section of the book. The interrelation of the autonomic nervous system with the endocrine system receives attention, with a thorough review of the literature on the nervous regulation of the hormones of the hypothesis and of the sympathetic, adrenal, and vagoinsulin systems. The integration of the autonomic and somatic nervous systems and somatic reactions to hypoglycemia, asphyxia, and anoxia, etc., makes up the third main portion of the book. The author concludes the book with a summary of the results of the physiologic investigations of autonomic reactions and the application of this material to clinical medicine, neurology, and neuropsychiatry. In all, the book is 300 odd pages long.

There has been need for this work for some time. It is a thorough integration of knowledge which heretofore has been spread through many journals over a number of years. It will be a valuable teaching aid for students of physiology and a source book for physiologists and clinicians with a physiologic approach to disease. For the new and growing field of psychosomatic medicine, *Autonomic Regulations* will serve as a guide and orientor to a physiologic approach, which is so important for the proper development in this young branch of Internal Medicine.

Dr. Gellhorn should be praised for his bibliography, which consists of eleven hundred references to the literature of the autonomic and endocrine systems and related subjects.

Biochemistry of the Skin†

MEDICAL students and clinicians would undoubtedly welcome a satisfactory volume dealing with the chemistry of the skin and changes which occur in disease. Dr. Markowitz' book completely fails to meet the need for such a study. The work is sprinkled with erroneous statements and misspelled words. The bibliography is poorly compiled. The inclusion of such subjects as basal metabolism and racial differences in blood, among others, seems hardly justifiable, while, on the other hand, the important and related subject of the chemistry of sweat is only briefly considered. The chapters on the vitamins and dermatoses contain noncritical discussion of subjects such as achromotrichia, the use of massive doses of vitamin D for psoriasis, and the relation of biotin to cancer. References to the author's clinical experience are few and superficial. The reviewer is left puzzled concerning the value the author attaches to the Caspari diet for malignancy, first described in 1929 and included in the appendix of this book.

Polarography‡

SINCE 1922 there has developed a new theory and practice for rapid qualitative and quantitative determinations of most metals and nonmetals as well as of many organic compounds. The method is considered of value in serologic examination for the detection of sulfhydryl containing compounds, unsaturated acids, carbonyl compounds, certain nitrogen

With 80 Illustrations and Frontispiece. Cloth, $5.50, 375 pages. Interscience Publishers, Inc., New York, 1943.

†Practical Survey of Chemistry and Metabolism of the Skin. By Morris Markowitz, M.D. Cloth, 196 pages, $3.50. The Blakiston Company, Philadelphia, 1942.

‡Polarography. Polarographic Analysis, Voltammetry and Amperometric Titrations. By I. M. Kolthoff, Professor and Head of Division of Analytical Chemistry, University of Minnesota, Minneapolis, Minn., and James J. Lingane, Instructor in Chemistry, University of California, Berkeley, California. First Edition with 141 Illustrations, 510 pages, $6.00. The Appendix contains tables of the Potentials of Common Reference Electrodes and of Half-Wave Potentials of Inorganic Substances. Eight pages can be bought separately, $0.75. Interscience Publishers, Inc., New York, 1941.

derivatives, and in making other biochemical assays. Any substance which can be electroreduced or electrooxidized can be detected and measured. The most desirable concentrations for analysis range between 10^{-4} and 10^{-2} molar, which on the average can be measured with a deviation of 2 per cent.

The analytic results of this new method depend on the interpretation of graphical current-voltage curves; hence the name "voltammetry" seems appropriate, but its founder Jaroslav Heyrovsky has called it *Polarography*. The decomposition potential of a given substance is characteristic of the particular electroreducible or electrooxidizable substance present. The "half-wave potential" is even more characteristic. The latter is recognized as the potential of the electrode in the solution of unknown against an external reference electrode, indicated by the point on a current-voltage curve where the current is equal to one-half of its limiting value. Under best conditions the limiting current is directly proportional to the concentration of the electroreducible substance. Thus, the "half-wave potential" shows the qualitative composition, while the limiting current measures quantitatively the unknown present, the interpretations being made by referring to curves of known substances. Even mixtures can often be assayed.

The authors have written a treatise, theoretical and practical, which compares with their usual high quality work. They have not only digested the information in all of the four hundred odd papers published on the subject up to 1940, but have supplied much information specifically by their own investigations. Due credit has been given to other workers, and sufficient bibliography has been supplied to aid those desiring more complete information. This book of 500 pages, the only important one written in English on Polarography, should be possessed by all interested in employing the methods and by those studying or teaching the subject.

Spectrophotometry in Medicine*

SPECTROPHOTOMETRIC methods are becoming of more and more importance in laboratory medicine; they are especially valuable in research work. This translation of Ludwig Heilmeyer's "Medizinische Spektrophotometrie" by A. Jordan and T. L. Tippell will be found of great value to any one interested either in the theory of spectrophotometry or its clinical application. Since this is primarily a translation of the original German version published in 1932, few references are made to methods developed since that time. The description of instruments, however, has been supplemented so as to bring it up-to-date. The subject matter is divided into 6 topics: (1) theory and selected methods of spectrophotometry; (2) the spectrophotometry of whole blood, of hemoglobin, and of the most important hemoglobin derivatives; (3) the first breakdown products of hemoglobin; (4) the spectrophotometry of blood serum and of normal and pathologic serum pigments; (5) the spectrophotometry of urine, and of the most important normal and pathologic urinary pigments; and (6) the spectrophotometry of bile, ascitic fluid, and cerebrospinal fluid.

*Translation of Ludwig Heilmeyer's "Medizinische Spektrophotometrie" by A. Jordan, M.B., B.S. (Lond.), D.Sc. (Strasbourg), M.R.C.P. (Lond.) Ingénieur-Chimiste E. C. M., Assistant-Pathologist E.M.S.; Jur[illegible] Chemical Pathology to St. Bartholomew's Hospital and T. L. Tippell. Clo[illegible] Adam Hilger Ltd., London, Eng., 1943. Obtainable in U. S. A. from The [illegible], 165 Newbury Street, Boston, Mass.
